Clinical Nephrology

Fourth Edition

Jürgen Floege, MD

Medizinische Klinik II
RWTH University of Aachen
Aachen, Germany

Richard J. Johnson, MD

Professor of Medicine
Division Chief
Temple Hoyne Buell and NKF of Colorado Endowed Chair of Medicine
University of Colorado, Denver
Aurora, Colorado

John Feehally, DM, FRCP

Professor of Renal Medicine
The John Walls Renal Unit
Leicester General Hospital
Leicester, United Kingdom

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Library of Congress Cataloging-in-Publication Data

Comprehensive clinical nephrology / [edited by] Jürgen Floege, Richard J. Johnson, John Feehally.—4th ed.

p. ; cm.

Includes bibliographical references and index.

ISBN 978-0-323-05876-6

1. Kidneys—Diseases. 2. Nephrology. I. Floege, Jürgen. II. Johnson, Richard J. (Richard Joseph). III. Feehally, John.

Sabre Foundation

To our mentors in nephrology—especially Bill Couser, Stewart Cameron, and Karl M. Koch

To our colleagues and collaborators, as well as others, whose research continues to light the way

*To our wives and families, who have once again endured the preparation of this fourth edition
with unfailing patience and support*

To our patients with renal disease, for whom it is a privilege to care

In the fourth edition of *Comprehensive Clinical Nephrology*, we continue to offer a text for fellows, practicing nephrologists, and internists that covers all aspects of the clinical work of the nephrologist, including fluid and electrolytes, hypertension, diabetes, dialysis, and transplantation. We recognize that this single volume does not compete with multivolume, highly referenced texts, and it remains our goal to provide “comprehensive” coverage of clinical nephrology yet also ensure that inquiring nephrologists can find the scientific issues and pathophysiology that underlie their clinical work.

For this edition all chapters have been extensively revised and updated in response to the advice and comments that we have received from many readers and colleagues. New features of the fourth edition include a chapter on inherited causes of nephrotic syndrome, an extended section on diabetic nephropathy, a

revised section on infectious diseases and the kidney, a revised and extended section on acute kidney injury, a chapter on herbal and over-the-counter medicines and the kidney, and an extended section on medical management of the kidney transplant recipient.

By popular demand we continue to offer readers access to the images from the book that we are pleased to see used in lectures and seminars in many parts of the world.

This is the first edition that features access to a companion Expert Consult website, with fully searchable text, a downloadable image library, and links to PubMed.

Renal Anatomy

Wilhelm Kriz, Marlies Elger

The complex structure of the mammalian kidney is best understood in the unipapillary form that is common to all small species. [Figure 1.1](#) is a schematic coronal section through such a kidney with a cortex enclosing a pyramid-shaped medulla, the tip of which protrudes into the renal pelvis. The medulla is divided into an outer and an inner medulla; the outer medulla is further subdivided into an outer and an inner stripe.

STRUCTURE OF THE KIDNEY

The specific components of the kidney are the nephrons, the collecting ducts, and a unique microvasculature.¹ The multipapillary kidney of humans contains roughly one million nephrons; however, the number is quite variable. This number is already established during prenatal development; after birth, new nephrons cannot be developed, and a lost nephron cannot be replaced.

Nephrons

A nephron consists of a renal corpuscle (glomerulus) connected to a complicated and twisted tubule that finally drains into a collecting duct ([Figs. 1.2 and 1.3](#)). By the location of renal corpuscles within the cortex, three types of nephron can be distinguished: superficial, midcortical, and juxtamedullary nephrons. The tubular part of the nephron consists of a proximal tubule and a distal tubule connected by Henle's loop² (see later discussion). There are two types of nephron, those with long Henle's loops and those with short loops. Short loops turn back in the outer medulla or even in the cortex (cortical loops). Long loops turn back at successive levels of the inner medulla.

Collecting Ducts

A collecting duct is formed in the renal cortex when several nephrons join. A connecting tubule (CNT) is interposed between a nephron and a cortical collecting duct. Cortical collecting ducts descend within the medullary rays of the cortex. They traverse the outer medulla as unbranched tubes. On entering the inner medulla, they fuse successively and open finally as papillary ducts into the renal pelvis (see [Figs. 1.2 and 1.3](#)).

Microvasculature

The microvascular pattern of the kidney ([Fig. 1.4](#); see also [Fig. 1.1](#)) is also similarly organized in mammalian species.^{1,3} The renal artery, after entering the renal sinus, finally divides into the interlobar arteries, which extend toward the cortex in the space between the wall of the pelvis (or calyx) and the adjacent cortical

tissue. At the junction between cortex and medulla, they divide and pass over into the arcuate arteries, which also branch. They give rise to the cortical radial arteries (interlobular arteries) that ascend radially through the cortex. No arteries penetrate the medulla.

Afferent arterioles generally arise from cortical radial arteries; they supply the glomerular tufts. Agglomerular tributaries to the capillary plexus are rarely found. As a result, the blood supply of the peritubular capillaries of the cortex and the medulla is exclusively postglomerular. Glomeruli are drained by efferent arterioles. Two basic types can be distinguished: cortical and juxtamedullary efferent arterioles. Cortical efferent arterioles, which derive from superficial and midcortical glomeruli, supply the capillary plexus of the cortex.

The efferent arterioles of juxtamedullary glomeruli represent the supplying vessels of the renal medulla. Within the outer stripe of the medulla, they divide into the descending vasa recta and then penetrate the inner stripe in cone-shaped vascular bundles. At intervals, individual vessels leave the bundles to supply the capillary plexus at the adjacent medullary level.

Ascending vasa recta drain the renal medulla. In the inner medulla, they arise at every level, ascending as unbranched vessels. They traverse the inner stripe within the vascular bundles. The ascending vasa recta that drain the inner stripe may either join the vascular bundles or ascend directly to the outer stripe between the bundles. All the ascending vasa recta traverse the outer stripe as individual wavy vessels with wide lumina interspersed among the tubules. Because true capillaries derived from direct branches of efferent arterioles are relatively scarce, it is the ascending vasa recta that form the capillary plexus of the outer stripe. Finally, the ascending vasa recta empty into arcuate veins.

The vascular bundles represent a countercurrent exchanger between the blood entering and that leaving the medulla. In addition, the organization of the vascular bundles results in a separation of the blood flow to the inner stripe from that to the inner medulla. Descending vasa recta supplying the inner medulla traverse the inner stripe within the vascular bundles. Therefore, blood flowing to the inner medulla has not been exposed previously to tubules of the inner or outer stripe. All ascending vasa recta originating from the inner medulla traverse the inner stripe within the vascular bundles; thus, blood that has perfused tubules of the inner medulla does not subsequently perfuse tubules of the inner stripe. However, the blood returning from either the inner medulla or the inner stripe afterward does perfuse the tubules of the outer stripe. It has been suggested that this arrangement in the outer stripe functions as the ultimate trap to prevent solute loss from the medulla.

Figure 1.1 Coronal section through a unipapillary kidney.

Figure 1.2 Nephrons and the collecting duct system. Shown are short-looped and long-looped nephrons, together with a collecting duct (not drawn to scale). Arrows denote confluence of further nephrons.

Subdivisions of the Nephron and Collecting Duct System

Section	Subsections
Nephron	
Renal corpuscle	Glomerulus: the term used most frequently to refer to the entire renal corpuscle Bowman's capsule
Proximal tubule	Convoluted part Straight part (pars recta) or thick descending limb of Henle's loop
Intermediate tubule	Descending part or thin descending limb of Henle's loop Ascending part or thin ascending limb of Henle's loop
Distal tubule	Straight part or thick ascending limb of Henle's loop: subdivided into a medullary and a cortical part; the latter contains in its terminal portion the macula densa Convoluted part
Collecting duct system	
Connecting tubule	Includes the arcades in most species
Collecting duct	Cortical collecting duct Outer medullary collecting duct subdivided into an outer and an inner stripe portion Inner medullary collecting duct subdivided into basal, middle, and papillary portions

Figure 1.3 Subdivisions of the nephron and collecting duct system.

The intrarenal veins accompany the arteries. Central to the renal drainage of the kidney are the arcuate veins, which, in contrast to arcuate arteries, do form real anastomosing arches at the corticomedullary border. They accept the veins from the cortex and the renal medulla. The arcuate veins join to form interlobar veins, which run alongside the corresponding arteries.

The intrarenal arteries and the afferent and efferent arterioles are accompanied by sympathetic nerve fibers and terminal axons representing the efferent nerves of the kidney.¹ Tubules have direct contact to terminal axons only when they are located around the arteries or the arterioles. As stated by Barajas,⁴ "the tubular innervation consists of occasional fibers adjacent to perivascular tubules." The density of nerve contacts to convoluted proximal tubules is low; contacts to straight proximal tubules, thick ascending loops of the limbs of Henle, and collecting ducts (located in the medullary rays and the outer medulla) have never been encountered. The vast majority of tubular portions have no direct relationships to nerve terminals. Afferent nerves of the kidney are commonly believed to be sparse.⁵

NEPHRON

Renal Glomerulus (Renal Corpuscle)

The glomerulus comprises a tuft of specialized capillaries attached to the mesangium, both of which are enclosed in a pouch-like extension of the tubule, that is, Bowman's capsule (Figs. 1.5 and 1.6). The capillaries together with the mesangium

Figure 1.4 Microvasculature of the kidney. Afferent arterioles supply the glomeruli and efferent arterioles leave the glomeruli and divide into the descending vasa recta, which together with the ascending vasa recta form the vascular bundles of the renal medulla. The vasa recta ascending from the inner medulla all traverse the inner stripe within the vascular bundles, whereas most of the vasa recta from the inner stripe of the outer medulla ascend outside the bundles. Both types traverse the outer stripe as wide, tortuous channels.

are covered by epithelial cells (podocytes) forming the visceral epithelium of Bowman's capsule. At the vascular pole, this is reflected to become the parietal epithelium of Bowman's capsule. At the interface between the glomerular capillaries and the mesangium on one side and the podocyte layer on the other side, the glomerular basement membrane (GBM) is developed. The space between both layers of Bowman's capsule represents the urinary space, which at the urinary pole continues as the tubule lumen.

On entering the tuft, the afferent arteriole immediately divides into several (two to five) primary capillary branches, each of which gives rise to an anastomosing capillary network representing a glomerular lobule. In contrast to the afferent arteriole, the efferent arteriole is already established inside the tuft by confluence of capillaries from each lobule.⁶ Thus, the efferent

Figure 1.5 Renal corpuscle and juxtaglomerular apparatus. (Modified with permission from reference 1.)

arteriole has a significant intraglomerular segment located within the glomerular stalk.

Glomerular capillaries are a unique type of blood vessel made up of nothing but an endothelial tube (Figs. 1.7 and 1.8). A small stripe of the outer aspect of this tube directly abuts the mesangium; a major part bulges toward the urinary space and is covered by the GBM and the podocyte layer. This peripheral portion of the capillary wall represents the filtration area. The glomerular mesangium represents the axis of a glomerular lobule to which the glomerular capillaries are attached.

Glomerular Basement Membrane

The GBM serves as the skeleton of the glomerular tuft. It represents a complexly folded sack with an opening at the glomerular hilum (see Fig. 1.5). The outer aspect of this GBM sack is completely covered with podocytes. The interior of the sack is filled with the capillaries and the mesangium. As a result, on its inner aspect, the GBM is in touch either with capillaries or with the mesangium. At any transition between these two locations, the GBM changes from a convex pericapillary to a concave perimesangial course; the turning points are called mesangial angles.

In electron micrographs of traditionally fixed tissue, the GBM appears as a trilaminar structure made up of a lamina densa

Figure 1.6 Longitudinal section through a glomerulus (rat). At the vascular pole, the afferent arteriole (AA), the efferent arteriole (EA), the extraglomerular mesangium (EGM), and the macula densa (MD) are seen. At the urinary pole, the parietal epithelium (PE) transforms into the proximal tubule (P). PO, podocyte. (Light microscopy; magnification $\times 390$.)

Figure 1.7 Peripheral portion of a glomerular lobule. This shows a capillary, the axial position of the mesangium, and the visceral epithelium (podocytes). At the capillary-mesangial interface, the capillary endothelium directly abuts the mesangium.

Figure 1.8 Glomerular capillary. **A**, The layer of interdigitating podocyte processes and the glomerular basement membrane (GBM) do not completely encircle the capillary. At the mesangial angles (arrows), both deviate from a pericapillary course and cover the mesangium. Mesangial cell processes, containing dense bundles of microfilaments (MF), interconnect the GBM and bridge the distance between the two mesangial angles. **B**, Filtration barrier. The peripheral part of the glomerular capillary wall comprises the endothelium with open pores (arrowheads), the GBM, and the interdigitating foot processes. The GBM shows a lamina densa bounded by the lamina rara interna and externa. The foot processes are separated by filtration slits bridged by thin diaphragms (arrows). (Transmission electron microscopy; magnification: **A**, $\times 8770$; **B**, $\times 50,440$.)

bounded by two less dense layers: the lamina rara interna and externa (see Fig. 1.8). Studies using freeze techniques reveal only one thick dense layer directly attached to the bases of the epithelium and endothelium.⁷

The major components of the GBM include type IV collagen, laminin, and heparan sulfate proteoglycans, as in basement membranes at other sites. Types V and VI collagen and nidogen have also been demonstrated. However, the GBM has several unique properties, notably a distinct spectrum of type IV collagen and laminin isoforms. The mature GBM is made up of type IV collagen consisting of $\alpha 3$, $\alpha 4$, and $\alpha 5$ chains (instead of $\alpha 1$ and $\alpha 2$ chains of most other basement membranes) and of laminin 11 consisting of $\alpha 5$, $\beta 2$, and $\gamma 1$ chains.⁸ Type IV collagen is the antigenic target in Goodpasture's disease (see Chapter 23), and mutations in the genes of the $\alpha 3$, $\alpha 4$, and $\alpha 5$ chains of type IV collagen are responsible for Alport's syndrome (see Chapter 46).

Current models depict the basic structure of the basement membrane as a three-dimensional network of type IV collagen.⁷ The type IV collagen monomer consists of a triple helix of length 400 nm that has a large noncollagenous globular domain at its C-terminal end called NC1. At the N terminus, the helix possesses a triple helical rod of length 60 nm: the 7S domain. Interactions between the 7S domains of two triple helices or the NC1 domains of four triple helices allow type IV collagen monomers to form dimers and tetramers. In addition, triple helical strands interconnect by lateral associations through binding of NC1 domains to sites along the collagenous region. This network is complemented by an interconnected network of laminin 11, resulting in a flexible, nonfibrillar polygonal assembly that is considered to provide mechanical strength to the basement membrane and to serve as a scaffold for alignment of other matrix components.

The electronegative charge of the GBM mainly results from the presence of polyanionic proteoglycans. The major proteoglycans of the GBM are heparan sulfate proteoglycans, among them perlecan and agrin. Proteoglycan molecules aggregate to form a meshwork that is kept highly hydrated by water molecules trapped in the interstices of the matrix.

Mesangium

Three major cell types occur within the glomerular tuft, all of which are in close contact with the GBM: mesangial cells, endothelial cells, and podocytes. In the rat, the numerical ratio has been calculated to be 2:3:1. The mesangial cells together with the mesangial matrix establish the glomerular mesangium. In addition, some studies suggest that macrophages bearing HLA-DR/Ia-like antigens may also rarely be found in the normal mesangium.

Mesangial Cells Mesangial cells are quite irregular in shape with many processes extending from the cell body toward the GBM (see Figs. 1.7 and 1.8). In these processes, dense assemblies of microfilaments are found that contain actin, myosin, and α -actinin.⁹ The processes are attached to the GBM either directly or through the interposition of microfibrils (see later discussion). The GBM represents the effector structure of mesangial contractility. Mesangial cell–GBM connections are especially prominent alongside the capillaries, interconnecting the two opposing mesangial angles of the GBM.

Mesangial Matrix The mesangial matrix fills the highly irregular spaces between the mesangial cells and the perimesangial GBM, anchoring the mesangial cells to the GBM.⁶ The ultrastructural organization of this matrix is incompletely understood. In specimens prepared by a technique that avoids osmium tetroxide and uses tannic acid for staining, a dense network of elastic microfibrils is seen. A large number of common extracellular matrix proteins have been demonstrated within the mesangial matrix, including several types of collagens (IV, V, and VI) and several components of microfibrillar proteins (fibrillin and the 31-kd microfibril-associated glycoprotein). The matrix also contains several glycoproteins (fibronectin is most abundant) as well as several types of proteoglycans.

Endothelium

Glomerular endothelial cells consist of cell bodies and peripherally located, attenuated, and highly fenestrated cytoplasmic sheets (see Figs. 1.7 and 1.8). Glomerular endothelial pores lack diaphragms, which are encountered only in the endothelium of

the final tributaries to the efferent arteriole.⁶ The round to oval pores have a diameter of 50 to 100 nm. The luminal membrane of endothelial cells is negatively charged because of its cell coat of several polyanionic glycoproteins, including podocalyxin. In addition, the endothelial pores are filled with sieve plugs mainly made up of sialoglycoproteins.¹⁰

Visceral Epithelium (Podocytes)

The visceral epithelium of Bowman's capsule comprises highly differentiated cells, the podocytes (Fig. 1.9; see also Fig. 1.7). In the developing glomerulus, podocytes have a simple polygonal shape. In rats, mitotic activity of these cells is completed soon after birth together with the cessation of the formation of new nephron anlagen. In humans, this point is already reached during prenatal life. The differentiation of the adult podocyte phenotype with the characteristic cell process pattern (see later discussion) is associated with the appearance of several podocyte-specific proteins, including podocalyxin, nephrin, podocin, synaptopodin, and GLEPP1.^{11,12} Differentiated podocytes are unable to replicate; therefore, in the adult, degenerated podocytes cannot be replaced. In response to an extreme mitogenic stimulation (e.g., by basic fibroblast growth factor 2), these cells may undergo mitotic nuclear division; however, the cells are unable to complete cell division, resulting in binucleated or multinucleated cells.¹²

Podocytes have a voluminous cell body that floats within the urinary space. The cell bodies give rise to long primary processes that extend toward the capillaries, to which they affix by their most distal portions and by an extensive array of foot processes.

Figure 1.9 Glomerular capillaries in the rat. The urinary side of the capillary is covered by the highly branched podocytes. The interdigitating system of primary processes (PP) and foot processes (FP) lines the entire surface of the tuft, extending also beneath the cell bodies. The foot processes of neighboring cells interdigitate but spare the filtration slits in between. (Scanning electron microscopy; magnification $\times 2200$.)

Figure 1.10 Glomerular filtration barrier. Two podocyte foot processes bridged by the slit membrane, the GBM, and the porous capillary endothelium are shown. The surfaces of podocytes and of the endothelium are covered by a negatively charged glycocalyx containing the sialoprotein podocalyxin (PC). The GBM is mainly composed of type IV collagen ($\alpha 3$, $\alpha 4$, and $\alpha 5$), laminin 11 ($\alpha 5$, $\beta 2$, and $\gamma 1$ chains), and the heparan sulfate proteoglycan agrin. The slit membrane represents a porous proteinaceous membrane composed of (as far as known) nephrin, NEPH1-3, P-cadherin, and FAT1. The actin-based cytoskeleton of the foot processes connects to both the GBM and the slit membrane. Regarding the connections to the GBM, $\beta_1\alpha_3$ integrin dimers specifically interconnect the TVP complex (talin, paxillin, vinculin) to laminin 11; the β - and α -dystroglycans interconnect utrophin to agrin. The slit membrane proteins are joined to the cytoskeleton by various adaptor proteins, including podocin, zonula occludens protein 1 (ZO-1; Z), CD2-associated protein (CD), and catenins (Cat). Among the nonselective cation channels (NSCC), TRPC6 associates with podocin (and nephrin, not shown) at the slit membrane. Only the angiotensin II (Ang II) type 1 receptor (AT₁) is shown as an example of the many surface receptors. Additional abbreviations: Cas, p130Cas; Ez, ezrin; FAK, focal adhesion kinase; ILK, integrin-linked kinase; M, myosin; N, NHERF2 (Na⁺-H⁺ exchanger regulatory factor); S, synaptopodin. (Modified from reference 11.)

The foot processes of neighboring podocytes regularly interdigitate with each other, leaving between them meandering slits (filtration slits) that are bridged by an extracellular structure, the slit diaphragm (Fig. 1.10; see also Figs. 1.7 to 1.9). Podocytes are polarized epithelial cells with a luminal and a basal cell membrane domain; the basal cell membrane domain corresponds to the sole plates of the foot processes that are embedded into the GBM. The border between basal and luminal membrane is represented by the slit diaphragm.¹³

The luminal membrane and the slit diaphragm are covered by a thick surface coat that is rich in sialoglycoproteins (including podocalyxin and podocin) and is responsible for the high negative surface charge of the podocytes. By comparison, the abluminal membrane (i.e., the soles of podocyte processes) contains specific transmembrane proteins that connect the cytoskeleton to the GBM. Two systems are known; first, $\alpha_3\beta_1$ integrin dimers, which interconnect the cytoplasmic focal adhesion proteins vinculin, paxillin, and talin with the $\alpha 3$, $\alpha 4$, and $\alpha 5$ chains of type IV collagen; and second, β - and α -dystroglycans, which interconnect the cytoplasmic adapter protein utrophin with agrin and laminin $\alpha 5$ chains in the GBM.¹¹ In addition, a subpodocyte space has also been recognized that can be altered by changes in ultrafiltration pressure and might theoretically be involved in the regulation of glomerular filtration.¹² Other membrane proteins, such as the C3b receptor and gp330/megalin, are present over the entire surface of podocytes.¹³

In contrast to the cell body (harboring a prominent Golgi system), the cell processes contain only a few organelles. A well-developed cytoskeleton accounts for the complex shape of the cells. In the cell body and the primary processes, microtubules and intermediate filaments (vimentin, desmin) dominate. Micro-

filaments form prominent U-shaped bundles arranged in the longitudinal axis of two successive foot processes in an overlapping pattern. Centrally, these bundles are linked to the microtubules of the primary processes; peripherally, they are linked to the GBM by integrins and dystroglycans (see previous discussion). α -Actinin 4 and synaptopodin establish the podocyte-specific bundling of the microfilaments.

The filtration slits (see Figs. 1.8 and 1.10) are the sites of convective fluid flow through the visceral epithelium. They have a constant width of about 30 to 40 nm. They are bridged by the slit diaphragm. This is a proteinaceous membrane whose molecular composition is presently not fully understood. Chemically fixed and tannic acid-treated tissue reveals a zipper-like structure with a row of pores approximately 14 nm² on either side of a central bar. At present, the following proteins are known to establish this membrane or to mediate its connection to the actin cytoskeleton of the foot processes: nephrin, P-cadherin, FAT1, NEPH1-3, and podocin.¹⁴ However, how these molecules interact with each other to establish a size-selective porous membrane is unknown.

Parietal Epithelium

The parietal epithelium of Bowman's capsule consists of squamous epithelial cells resting on a basement membrane (see Figs. 1.5 and 1.6). The flat cells are filled with bundles of actin filaments running in all directions. The parietal basement membrane differs from the GBM in that it comprises several proteoglycan-dense layers that, in addition to type IV, contain type XIV collagen. The predominant proteoglycan of the parietal basement membrane is a chondroitin sulfate proteoglycan.¹ Whereas the parietal epithelial cell was historically viewed as

simply composing the inside layer of Bowman's capsule, parietal epithelial cells were recently shown to represent endogenous stem cells, which can replace both podocytes and proximal tubular cells in health and in disease.¹⁵

Filtration Barrier

Filtration through the glomerular capillary wall occurs along an extracellular pathway including the endothelial pores, the GBM, and the slit diaphragm (see Figs. 1.8 and 1.10). All these components are quite permeable for water; the high permeability for water, small solutes, and ions results from the fact that no cell membranes are interposed. The hydraulic conductance of the individual layers of the filtration barrier is difficult to study. In a mathematical model of glomerular filtration, the hydraulic resistance of the endothelium was predicted to be small, whereas the GBM and filtration slits contribute roughly one half each to the total hydraulic resistance of the capillary wall.¹⁶

The barrier function of the glomerular capillary wall for macromolecules is selective for size, shape, and charge.¹³ The charge selectivity of the barrier results from the dense accumulation of negatively charged molecules throughout the entire depth of the filtration barrier, including the surface coat of endothelial cells, and the high content of negatively charged heparan sulfate proteoglycans in the GBM. Polyanionic macromolecules, such as plasma proteins, are repelled by the electronegative shield originating from these dense assemblies of negative charges.

The crucial structure accounting for the size selectivity of the filtration barrier appears to be the slit diaphragm.¹⁶ Uncharged macromolecules up to an effective radius of 1.8 nm pass freely through the filter. Larger components are more and more restricted (indicated by their fractional clearances, which progressively decrease) and are totally restricted at effective radii of more than 4 nm. Plasma albumin has an effective radius of 3.6 nm; without the repulsion from the negative charge, plasma albumin would pass through the filter in considerable amounts.

Stability of the Glomerular Tuft

The main challenge for the glomerular capillaries is to combine selective leakiness with stability. The walls of capillaries do not appear to be capable of resisting high transmural pressure gradients. Several structures and mechanisms are involved in counteracting the distending forces to which the capillary wall is constantly exposed. The locus of action of all these forces is the GBM.

Two systems appear to be responsible for the development of stabilizing forces. A basic system consists of the GBM and the mesangium. Cylinders of the GBM, in fact, largely define the shape of glomerular capillaries. These cylinders, however, do not completely encircle the capillary tube; they are open toward the mesangium. Mechanically, they are completed by contractile mesangial cell processes that bridge the gaps of the GBM between two opposing mesangial angles, permitting the development of wall tension.¹⁷

Podocytes act as a second structure-stabilizing system. Two mechanisms appear to be involved. First, in addition to mesangial cells, podocytes stabilize the folding pattern of glomerular capillaries by fixing the turning points of the GBM between neighboring capillaries (mesangial cells from inside, podocytes from outside).¹⁷ Second, podocytes may contribute to structural stability of glomerular capillaries by a mechanism similar to that of pericytes elsewhere in the body. Podocytes are attached to the GBM by foot processes that cover almost entirely the outer aspect of the GBM. The foot processes possess a well-developed

contractile system connected to the GBM. Because the foot processes are attached at various angles on the GBM, they may function as numerous small, stabilizing patches on the GBM, counteracting locally the elastic distention of the GBM.⁹

Renal Tubule

The renal tubule is subdivided into several distinct segments: a proximal tubule, an intermediate tubule, a distal tubule, a CNT, and the collecting duct (see Figs. 1.1 and 1.3).¹² Henle's loop comprises the straight part of the proximal tubule (representing the thick descending limb), the thin descending and the thin ascending limbs (both thin limbs together represent the intermediate tubule), and the thick ascending limb (representing the straight portion of the distal tubule), which includes the macula densa. The CNT and the various collecting duct segments form the collecting duct system.

The renal tubules are outlined by a single-layer epithelium anchored to a basement membrane. The epithelium is a transporting epithelium consisting of flat or cuboidal epithelial cells connected apically by a junctional complex consisting of a tight junction (zonula occludens), an adherens junction, and, rarely, a desmosome. As a result of this organization, two different pathways through the epithelium exist (Fig. 1.11): a transcellular pathway, including the transport across the luminal and the basolateral cell membrane and through the cytoplasm; and a paracellular pathway through the junctional complex and the lateral intercellular spaces. The functional characteristics of the paracellular transport are determined by the tight junction, which differs markedly in its elaboration in the various tubular segments. The transcellular transport is determined by the specific channels, carriers, and transporters included in the apical and basolateral cell membranes. The various nephron segments differ markedly in function, distribution of transport proteins, and responsiveness to hormones and drugs such as diuretics.

Proximal Tubule

The proximal tubule reabsorbs the bulk of filtered water and solutes (Fig. 1.12). The epithelium shows numerous structural

Figure 1.11 Tubular epithelia. Transport across the epithelium may follow two routes: transcellular across luminal and basolateral membranes and paracellular through the tight junction and intercellular spaces.

Figure 1.12 Tubules of the renal cortex. **A**, Proximal convoluted tubule is equipped with a brush border and a prominent vacuolar apparatus in the apical cytoplasm. The rest of the cytoplasm is occupied by a basal labyrinth consisting of large mitochondria associated with basolateral cell membranes. (Transmission electron microscopy; magnification $\times 1530$.) **B**, Distal convoluted tubule also has interdigitated basolateral cell membranes intimately associated with large mitochondria; in contrast to the proximal tubule, the apical surface is amplified only by some stubby microvilli. (Transmission electron microscopy; magnification $\times 1830$.)

adaptations to this role. The proximal tubule has a prominent brush border (increasing the luminal cell surface area) and extensive interdigitation by basolateral cell processes (increasing the basolateral cell surface area). This lateral cell interdigitation extends up to the leaky tight junction, thus increasing the tight junctional belt in length and providing a greatly increased passage for the passive transport of ions. Proximal tubules have large prominent mitochondria intimately associated with the basolateral cell membranes where the Na^+, K^+ -adenosine triphosphatase (ATPase) is located; this machinery dominates the transcellular

transport. The luminal transporter for Na^+ entry specific for the proximal tubule is the Na^+-H^+ exchanger. The high hydraulic permeability for water is rooted in abundant occurrence of the water channel protein aquaporin 1. A prominent lysosomal system is known as the apical vacuolar endocytotic apparatus and is responsible for the reabsorption of macromolecules (polypeptides and proteins such as albumin) that have passed through the glomerular filter. The proximal tubule is generally subdivided into three segments (known as S_1 , S_2 , S_3 , or P_1 , P_2 , P_3) that differ considerably in cellular organization and, consequently, also in function.¹⁸

Henle's Loop

Henle's loop consists of the straight portion of the proximal tubule, the thin descending and (in long loops) thin ascending limbs, and the thick ascending limb (Fig. 1.13; see also Fig. 1.2). The thin descending limb, like the proximal tubule, is highly permeable for water (the channels are of aquaporin 1), whereas, beginning exactly at the turning point, the thin ascending limb is impermeable for water. The specific transport functions of the thin limbs contributing to the generation of the osmotic medullary gradient are under debate.

The thick ascending limb is often called the diluting segment. It is water impermeable but reabsorbs considerable amounts of salt, resulting in the separation of salt from water. The salt is trapped in the medulla, whereas the water is carried away into the cortex, where it may return into the systemic circulation. The specific transporter for Na^+ entry in this segment is the luminal $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ cotransporter, which is the target of diuretics such as furosemide. The tight junctions of the thick ascending limb have a comparatively low permeability. The cells heavily interdigitate by basolateral cell processes, associated with large mitochondria supplying the energy for the transepithelial transport. The cells synthesize a specific protein, the Tamm-Horsfall protein, and release it into the tubular lumen. This protein is thought to be important later for preventing the formation of kidney stones. In contrast to the proximal tubule, the luminal membrane is only sparsely amplified by microvilli. Just before the transition to the distal convoluted tubule, the thick ascending limb contains the macula densa, which adheres to the parent glomerulus (see Juxtaglomerular Apparatus).

Distal Convoluted Tubule

The epithelium is fairly highly differentiated, exhibiting the most extensive basolateral interdigitation of the cells and the greatest density of mitochondria in all nephron portions (see Fig. 1.12). Apically, the cells are equipped with numerous microvilli. The specific Na^+ transporter of the distal convoluted tubule is the luminal Na^+-Cl^- cotransporter, which is the target of thiazide diuretics.

COLLECTING DUCT SYSTEM

The collecting duct system (see Fig. 1.2) includes the CNT and the cortical and medullary collecting ducts. Two nephrons may join at the level of the CNT, forming an arcade that, cytologically, is a CNT. Two types of cell line the CNT: the CNT cell, which is specific to the CNTs; and the intercalated (IC) cell, which also occurs later in the collecting duct. The CNT cells are similar to the collecting duct cells (CD cells) in cellular organization. Both cell types share sensitivity to vasopressin (antidiuretic hormone [ADH]; see later discussion); the CNT cell, however, lacks sensitivity to mineralocorticoids.

Figure 1.13 Tubules in the medulla. **A**, Cross section through the inner stripe of the outer medulla. A descending thin limb of a long loop (DL), the medullary thick ascending limbs (AL), and a collecting duct (CD) with principal cells (P) and intercalated cells (IC) are shown. C, peritubular capillaries; F, fibroblast. **B**, In the inner medulla cross section, thin descending and ascending limbs (TL), a collecting duct (CD), and vasa recta (VR) are seen. (Transmission electron microscopy; magnification: **A**, $\times 990$; **B**, $\times 1120$.)

Collecting Ducts

The collecting ducts (see Fig. 1.13) may be subdivided into cortical and medullary ducts, and the medullary ducts into outer and inner; the transitions are gradual. Like the CNT, the collecting ducts are lined by two types of cell: CD cells (principal cells) and IC cells. The IC cells decrease in number as the collecting duct descends into the medulla and are absent from the papillary collecting ducts.

The CD cells (Fig. 1.14A) are simple, polygonal cells increasing in size toward the tip of the papilla. The basal surface of these cells is characterized by invaginations of the basal cell membrane (basal infoldings). The tight junctions have a large apicobasal depth, and the apical cell surface has a prominent glycocalyx. Along the entire collecting duct, these cells contain a luminal shuttle system for aquaporin 2 under the control of vasopressin, providing the potential to switch the water permeability of the collecting ducts from zero (or at least from low) to permeable.¹⁹ A luminal amiloride-sensitive Na^+ channel is involved in the responsiveness of cortical collecting ducts to aldosterone. The terminal portions of the collecting duct in the inner medulla express the urea transporter UTB1, which, in an ADH-dependent fashion, accounts for the recycling of urea, a process that is crucial in the urine-concentrating mechanism.²⁰

The second cell type, the IC cell (Fig. 1.14B), is present in both the CNT and the collecting duct. There are at least two types of IC cells, designated A and B cells, distinguished on the basis of structural, immunocytochemical, and functional

Figure 1.14 Collecting duct cells. **A**, Principal cell (CD cell) of a medullary collecting duct. The apical cell membrane bears some stubby microvilli covered by a prominent glycocalyx; the basal cell membrane forms invaginations. Note the deep tight junction. **B**, Intercalated cells, type A. Note the dark cytoplasm (dark cells) with many mitochondria and apical microfolds; the basal membrane forms invaginations. (Transmission electron microscopy; magnification: **A**, $\times 8720$; **B**, $\times 6970$.)

characteristics. Type A cells have been defined as expressing H^+ -ATPase at their luminal membrane; they secrete protons. Type B cells express the H^+ -ATPase at their basolateral membrane; they secrete bicarbonate ions and reabsorb protons.²¹

With these different cell types, the collecting ducts are the final regulators of fluid and electrolyte balance, playing important roles in the handling of Na^+ , Cl^- , and K^+ as well as acid and base. The responsiveness of the collecting ducts to vasopressin enables an organism to live in arid conditions, allowing it to produce a concentrated urine and, if necessary, a dilute urine.

JUXTAGLOMERULAR APPARATUS

The juxtaglomerular apparatus (see Fig. 1.5) comprises the macula densa, the extraglomerular mesangium, the terminal portion of the afferent arteriole with its renin-producing granular cells (nowadays also often termed juxtaglomerular cells), and the beginning portions of the efferent arteriole.

The macula densa (Fig. 1.15A; see also Fig. 1.6) is a plaque of specialized cells in the wall of the thick ascending limb at the site where the limb attaches to the extraglomerular mesangium of the parent glomerulus. The most obvious structural feature is the narrowly packed cells with large nuclei, which account for the name macula densa. The cells are anchored to a basement membrane, which blends with the matrix of the extraglomerular mesangium.¹ The cells are joined by tight junctions with very low permeability and have prominent lateral intercellular spaces. The width of these spaces varies under different functional conditions.¹ The most conspicuous immunocytochemical difference between macula densa cells and any other epithelial cell of the nephron is the high content of neuronal nitric oxide synthase 1²² and of cyclooxygenase 2.²³

The basal aspect of the macula densa is firmly attached to the extraglomerular mesangium, which represents a solid complex of cells and matrix that is penetrated neither by blood vessels nor by lymphatic capillaries (see Figs. 1.5 and 1.15A). Like the mesangial cells proper, extraglomerular mesangial cells are heavily branched. Their processes, interconnected among each other by gap junctions, contain prominent bundles of microfilaments and are connected to the basement membrane of Bowman's capsule as well as to the walls of both glomerular arterioles. As a whole, the extraglomerular mesangium interconnects all structures of the glomerular entrance.⁶

The granular cells are assembled in clusters within the terminal portion of the afferent arteriole (Fig. 1.15B), replacing ordinary smooth muscle cells. Their name refers to the specific cytoplasmic granules in which renin, the major secretion product of these cells, is stored. They are the main site of the body where renin is secreted. Renin release occurs by exocytosis into the surrounding interstitium. Granular cells are connected to the extraglomerular mesangial cells, to adjacent smooth muscle cells, and to endothelial cells by gap junctions. They are densely innervated by sympathetic nerve terminals. Granular cells are modified smooth muscle cells; under conditions requiring enhanced renin synthesis (e.g., volume depletion or stenosis of the renal artery), additional smooth muscle cells located upstream in the wall of the afferent arteriole may transform into granular cells.

The structural organization of the juxtaglomerular apparatus suggests a regulatory function. There is agreement that some component of the distal urine (probably Cl^-) is sensed by the macula densa, and this information is used first to adjust the tone of the glomerular arterioles, thereby producing a change in glomerular blood flow and filtration rate. Even if many details of

Figure 1.15 Juxtaglomerular apparatus. A, Macula densa of a thick ascending limb. The cells have prominent nuclei and lateral intercellular spaces. Basally, they attach to the extraglomerular mesangium (EGM). B, Afferent arteriole near the vascular pole. this mechanism are still subject to debate, the essence of this system has been verified by many studies, and it is known as the tubular glomerular feedback mechanism.²⁴ Second, this system determines the amount of renin that is released, through the interstitium, into the circulation, thereby acquiring great systemic relevance.

RENAL INTERSTITIUM

The interstitium of the kidney is comparatively sparse. Its fractional volume in the cortex ranges from 5% to 7% (with a tendency to increase with age). It increases across the medulla from cortex to papilla: in the outer stripe, it is 3% to 4% (the lowest

Figure 1.16 Renal dendritic cells. Dendritic cells (CX₃CR1⁺ cells, green) surrounding tubular segments in the medulla of mice (three-dimensional reconstruction). (Reprinted with permission from reference 26.)

value of all kidney zones; this is interpreted as forming a barrier to prevent loss of solutes from a hyperosmolar medulla into the cortex); in the inner stripe, it is 10%; and in the inner medulla, it is up to ~30%. The cellular constituents of the interstitium are resident fibroblasts, which establish the scaffold frame for renal corpuscles, tubules, and blood vessels. In addition, there are varying numbers of migrating cells of the immune system, especially dendritic cells. The space between the cells is filled with extracellular matrix, namely, ground substance (proteoglycans, glycoproteins), fibrils, and interstitial fluid.²⁵

From a morphologic point of view, fibroblasts are the central cells in the renal interstitium. They are interconnected by specialized contacts and adhere by specific attachments to the basement membranes surrounding the tubules, the renal corpuscles, the capillaries, and the lymphatics.

Renal fibroblasts are difficult to distinguish from interstitial dendritic cells on a morphologic basis because both may show a stellate cellular shape and both display substantial amounts of mitochondria and endoplasmic reticulum. They may, however, easily be distinguished by immunocytochemical techniques. Dendritic cells constitutively express the major histocompatibility complex class II antigen and may express antigens such as CD11c. Dendritic cells may have an important role in maintaining peripheral tolerance in the kidney (Fig. 1.16).²⁶ In contrast, fibroblasts in the renal cortex (not in the medulla) contain the enzyme ecto-5'-nucleotidase (5'-NT).²⁷ A subset of 5'-NT-positive fibroblasts of the renal cortex synthesize epoetin.²⁷ Under normal conditions, these fibroblasts are exclusively found within the juxtamedullary portions of the cortical labyrinth. When there is an increasing demand for epoetin, the synthesizing cells extend to more superficial portions of the cortical labyrinth and, to a lesser degree, to the medullary rays.²⁸

Fibroblasts within the medulla, especially within the inner medulla, have a particular phenotype known as lipid-laden interstitial cells. The cells are oriented strictly perpendicularly toward the longitudinal axis of the tubules and vessels (running all in parallel) and contain conspicuous lipid droplets. These fibroblasts of the inner medulla produce large amounts of glycosaminoglycans and, possibly related to the lipid droplets, vasoactive lipids, in particular prostaglandin E₂.²⁶

The intrarenal arteries are accompanied by a prominent sheath of loose interstitial tissue (Fig. 1.17); the renal veins are in apposition to this sheath but not included in it. Intrarenal nerve fibers and lymphatics run within this periarterial tissue. Lymphatics start in the vicinity of the afferent arteriole and leave the kidney running within the periarterial tissue sheath toward the hilum. Together with the lymphatics, the periarterial tissue

Figure 1.17 Intrarenal arteries in a periarterial connective tissue sheath. Cross section through a cortical radial artery surrounded by the sheath containing the renal nerves (N) and lymphatics (Ly). A vein lies outside the sheath. (Transmission electron microscopy; magnification ×830.)

constitutes a pathway for interstitial fluid drainage of the renal cortex; the renal medulla has no lymphatic drainage.

Renal Physiology

David G. Shirley, Robert J. Unwin

The prime function of the “kidneys” is to maintain a stable *milieu intérieur* by the selective retention or elimination of water, electrolytes, and other solutes. This is achieved by three processes: (1) filtration of circulating blood from the glomerulus to form an ultrafiltrate of plasma in Bowman’s space; (2) selective reabsorption (from tubular fluid to blood) across the cells lining the renal tubule; and (3) selective secretion (from peritubular capillary blood to tubular fluid).

GLOMERULAR STRUCTURE AND ULTRASTRUCTURE

The process of urine formation begins by the production of an ultrafiltrate of plasma. Chapter 1 provides a detailed description of glomerular anatomy and ultrastructure; therefore, only the brief essentials for an understanding of how the ultrafiltrate is formed are given here. The pathway for ultrafiltration of plasma from the glomerulus to Bowman’s space consists of the fenestrated capillary endothelium, the capillary basement membrane, and the visceral epithelial cell layer (podocytes) of Bowman’s capsule; the podocytes have large cell bodies and make contact with the basement membrane only by cytoplasmic foot processes. Mesangial cells, which fill the spaces between capillaries, have contractile properties and are capable of altering the capillary surface area available for filtration.

Filtration is determined principally by the molecular size and shape of the solute and, to a much lesser extent, by its charge. The size cutoff is not absolute; resistance to filtration begins at an effective molecular radius of slightly less than 2 nm, and substances with an effective radius exceeding ~4 nm are not filtered at all. The fenestrations between capillary endothelial cells have a diameter of 50 to 100 nm, and the podocyte foot processes have gaps between them (filtration slits) with a diameter of 25 to 50 nm, but they are bridged by diaphragms (the slit diaphragms), which are themselves penetrated by small pores. The slit diaphragms constitute the main filtration barrier, although both the endothelium (by preventing the passage of blood cells) and the basement membrane contribute.¹ In addition, the podocytes and the endothelial cells are covered by a glycocalyx composed of negatively charged glycoproteins, glycosaminoglycans, and proteoglycans, and the basement membrane is rich in heparan sulfate proteoglycans. This accumulation of fixed negative charges further restricts the filtration of large negatively charged ions, mainly proteins (Fig. 2.1). This explains why albumin, despite an effective radius (3.6 nm) that would allow significant filtration based on size alone, is normally virtually excluded. If

these fixed negative charges are lost, as in some forms of early or mild glomerular disease (e.g., minimal change nephropathy), albumin filterability increases and proteinuria results.

GLOMERULAR FILTRATION RATE

At the level of the single glomerulus, the driving force for glomerular filtration (the *net ultrafiltration pressure*) is determined by the net hydrostatic and oncotic (colloid osmotic) pressure gradients between glomerular plasma and the filtrate in Bowman’s space. The rate of filtration (single-nephron glomerular filtration rate) is determined by the product of the net ultrafiltration pressure and the *ultrafiltration coefficient*, a composite of the surface area available for filtration and the hydraulic conductivity of the glomerular membranes. Therefore, the single-nephron glomerular filtration rate is

$$K_f[(P_{gc} - P_{bs}) - (\pi_{gc} - \pi_{bs})]$$

where K_f is the ultrafiltration coefficient, P_{gc} is glomerular capillary hydrostatic pressure (~45 mm Hg), P_{bs} is Bowman’s space hydrostatic pressure (~10 mm Hg), π_{gc} is glomerular capillary oncotic pressure (~25 mm Hg), and π_{bs} is Bowman’s space oncotic pressure (0 mm Hg). Thus, net ultrafiltration pressure is around 10 mm Hg at the afferent end of the capillary tuft. As filtration of protein-free fluid proceeds along the glomerular capillaries, π_{gc} increases (because plasma proteins are concentrated into a smaller volume of glomerular plasma) and, at a certain point toward the efferent end, π_{gc} may equal the net hydrostatic pressure gradient; that is, the net ultrafiltration pressure may fall to zero: so-called *filtration equilibrium* (Fig. 2.2). In humans, complete filtration equilibrium is approached but rarely if ever achieved.

The total rate at which fluid is filtered into all the nephrons (glomerular filtration rate [GFR]) is typically ~120 ml/min per 1.73 m² surface area, but the normal range is wide. GFR can be measured by use of renal clearance techniques. The renal clearance of any substance not metabolized by the kidneys is the volume of plasma required to provide that amount of the substance excreted in the urine per unit time; this virtual volume can be expressed mathematically as

$$C_y = U_y \times V / P_y$$

where C_y is the renal clearance of y , U_y is the urine concentration of y , V is the urine flow rate, and P_y is the plasma concentration of y . If a substance is freely filtered by the glomerulus and is not

Figure 2.1 Size and charge barrier: effects of size and electrical charge on filterability. **A**, Normal kidney. **B**, Loss of fixed negative charges. A 100% filterability indicates that the substance is freely filtered, that is, its concentration in Bowman's space equals that in glomerular capillary plasma. For molecules and small ions (e.g., Na^+ , Cl^-), charge has no effect on filterability; but for ions whose effective molecular radius exceeds ~1.6 nm, anions are filtered less easily than neutral molecules or cations. Thus, insignificant amounts of albumin (anion) are normally filtered. If the fixed negative charges of the glomerular basement membranes are lost, as in early minimal change nephropathy, charge no longer influences filterability; consequently, significant albumin filtration occurs.

reabsorbed or secreted by the tubule, its renal clearance equals GFR; that is, it measures the volume of plasma filtered through the glomeruli per unit time. The various methods for measurement of GFR and their pitfalls are discussed in Chapter 3.

MEASUREMENT OF RENAL PLASMA FLOW

The use of the clearance technique and the availability of substances that undergo both glomerular filtration and virtually complete tubular secretion have made it possible to measure renal plasma flow (RPF; typically ~650 ml/min). *p*-Aminohippurate (PAH) is an organic acid that is filtered by the glomerulus and actively secreted by the proximal tubule. When the plasma concentration of PAH is lower than 10 mg/dl, most of the PAH reaching the peritubular capillaries is cleared by tubular secretion and little PAH appears in renal venous plasma. Under these

Figure 2.2 Glomerular filtration pressures along a glomerular capillary. The hydrostatic pressure gradient ($\Delta P = P_{gc} - P_{bs}$) is relatively constant along the length of a capillary, whereas the opposing oncotic pressure gradient ($\Delta\pi = \pi_{gc}$) increases as protein-free fluid is filtered, thereby reducing net ultrafiltration pressure. Two curves are shown, one where filtration equilibrium is reached and one where it is merely approached.

circumstances, the amount of PAH transferred from the plasma to the tubular lumen through filtration and secretion (i.e., the amount found in the final urine) approximates the amount of PAH delivered to the kidneys in the plasma. Therefore,

$$\text{RPF} \times P_{\text{PAH}} = U_{\text{PAH}} \times V$$

or

$$\text{RPF} = (U_{\text{PAH}} \times V) / P_{\text{PAH}} = \text{PAH clearance}$$

where U_{PAH} and P_{PAH} are the concentrations of PAH in the urine and plasma, respectively, and V is the urine flow rate. Renal blood flow (RBF) can be calculated as

$$\text{RBF} = [\text{RPF} / (100 - \text{hematocrit})] \times 100$$

and is typically ~1200 ml/min.

The most important limitation of this method is the renal extraction of PAH, which is always less than 100%. At high plasma concentrations (>10 to 15 mg/dl), fractional tubular secretion of PAH declines and significant amounts appear in the renal veins; under these circumstances PAH clearance seriously underestimates RPF. There are also diseases that can produce either toxins or weak organic acids (e.g., liver and renal failure) that interfere with PAH secretion or cause tubular damage leading to inhibition of PAH transport. Finally, certain drugs, like probenecid, are organic acids and compete with PAH for tubular secretion, thereby reducing PAH clearance.

Figure 2.3 Renal autoregulation of renal blood flow and glomerular filtration rate. If mean arterial blood pressure is in the range of ~80 to 180 mm Hg, fluctuations in blood pressure have only marginal effects on renal blood flow and glomerular filtration rate. This is an intrinsic mechanism and can be modulated or overridden by extrinsic factors.

AUTOREGULATION OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Although acute variations in arterial blood pressure inevitably cause corresponding changes in RBF and GFR, they are short lived, and provided the blood pressure remains within the normal range, compensatory mechanisms come into play after a few seconds to return both RBF and GFR toward normal.² This is the phenomenon of *autoregulation* (Fig. 2.3). Autoregulation is effected primarily at the level of the afferent arterioles and is believed to result from a combination of two mechanisms:

1. a *myogenic reflex*, whereby the afferent arteriolar smooth muscle wall constricts automatically when renal perfusion pressure rises; and
2. *tubuloglomerular feedback* (TGF), whereby an increased delivery of NaCl to the macula densa region of the nephron (a specialized plaque of cells situated at the distal end of the loop of Henle), resulting from increases in renal perfusion pressure, causes vasoconstriction of the afferent arteriole supplying that nephron's glomerulus.

Because these mechanisms restore both RBF and P_{gc} toward normal, the initial change in GFR is also reversed. The TGF system is possible because of the *juxtaglomerular apparatus*, which consists of the macula densa region of each nephron and the adjacent glomerulus and afferent and efferent arterioles (Fig. 2.4). The primary mediator of TGF is adenosine triphosphate (ATP). Increased NaCl delivery to the macula densa leads to increased NaCl uptake by these cells, which triggers ATP release into the surrounding extracellular space.³ It is thought that ATP has a direct vasoconstrictor effect, acting on P2X₁ purinoceptors on afferent arteriolar cells; but there is also good evidence that nucleotidases present in this region degrade ATP to adenosine, which, acting on afferent arteriolar A₁ receptors, can also cause vasoconstriction.⁴ The sensitivity of TGF is modulated by locally

Figure 2.4 Tubuloglomerular feedback. Changes in the delivery of NaCl to the macula densa region of the thick ascending limb of the loop of Henle cause changes in the afferent arteriolar caliber. The response is mediated by adenosine or possibly adenosine triphosphate (ATP), and modulated by other locally produced agents, such as angiotensin II and nitric oxide. Increased macula densa NaCl delivery results in afferent arteriolar constriction, thereby reducing GFR.

produced angiotensin II (Ang II), nitric oxide, and certain eicosanoids (see later discussion).

Despite renal autoregulation, a number of extrinsic factors (nervous and humoral) can alter renal hemodynamics. Independent or unequal changes in the resistance of afferent and efferent arterioles, together with alterations in K_f (thought to result largely from mesangial cell contraction and relaxation), can result in disproportionate or even contrasting changes in RBF and GFR. In addition, within the kidney, changes in vascular resistance in different regions of the renal cortex can alter the distribution of blood flow, for example, diversion of blood from outer to inner cortex in hemorrhagic shock.⁵ Figure 2.5 indicates how, in principle, changes in afferent and efferent arteriolar resistance will affect net ultrafiltration. Several important vasoactive factors that alter renal hemodynamics are listed in Figure 2.6 and discussed at the end of the chapter. In addition, studies suggest that disease of the renal afferent arteriole, such as occurs in hypertension and progressive kidney disease, may also interfere with renal autoregulatory mechanisms.

TUBULAR TRANSPORT

Vectorial transport, that is, net movement of substances from tubular fluid to blood (reabsorption) or vice versa (secretion), requires that the cell membrane facing the tubular fluid (*luminal* or *apical*) has properties different from those of the membrane facing the blood (*peritubular* or *basolateral*). In this polarized epithelium, certain transport proteins are located in one membrane, and others are located in the other, thus allowing the net movement of substances across the cell (transcellular route). The *tight junction*, which is a contact point close to the apical side of adjacent cells, limits water and solute movement between cells (paracellular route).

Solute transport across cell membranes uses either passive or active mechanisms.

Passive Transport

1. *Simple diffusion* always occurs down an electrochemical gradient, which is a composite of the concentration gradient

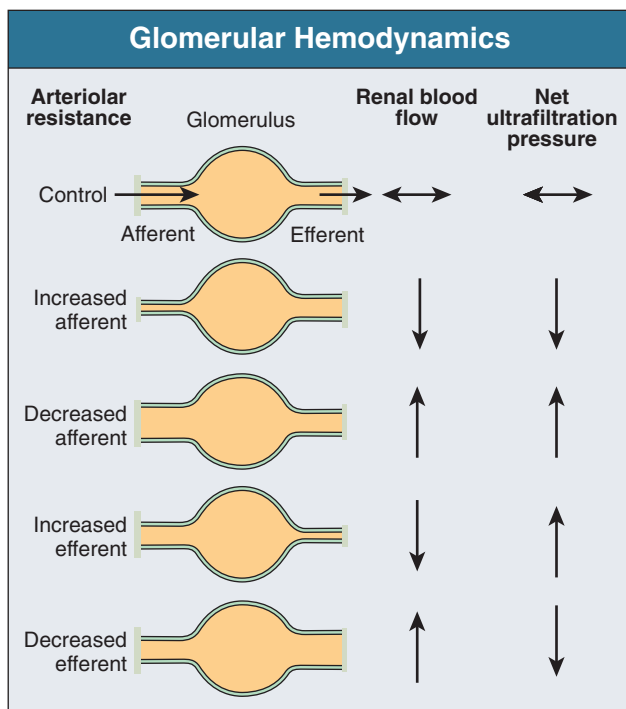

Figure 2.5 Glomerular hemodynamics. Changes in afferent or efferent arteriolar resistance will alter renal blood flow and (usually) net ultrafiltration pressure. However, the effect on ultrafiltration pressure depends on the relative changes in afferent and efferent arteriolar resistance. The overall effect on glomerular filtration rate will depend not only on renal blood flow and net ultrafiltration pressure, but also on the ultrafiltration coefficient (K_f ; see Fig. 2.6).

and the electrical gradient. In the case of an undissociated molecule, only the concentration gradient is relevant; whereas for a charged ion, the electrical gradient must also be considered. Simple diffusion does not require a direct energy source, although an active transport process (see later discussion) is usually necessary to establish the initial concentration and electrical gradients.

2. **Facilitated diffusion** (or carrier-mediated diffusion) depends on an interaction of the molecule or ion with a specific membrane carrier protein that eases, or facilitates, its passage across the cell membrane's lipid bilayer. In almost all instances of carrier-mediated transport in the kidney, two or more ions or molecules share the carrier, one moiety moving down its electrochemical gradient, the other against (see later discussion).
3. **Diffusion through a membrane channel** (or pore) formed by specific integral membrane proteins is also a form of facilitated diffusion because it allows charged and lipophobic molecules to pass through the membrane at a high rate.

Active Transport

When an ion is moved directly against an electrochemical gradient ("uphill"), a source of energy is required, and this is known as active transport. In cells, this energy is derived from metabolism: ATP production and its hydrolysis. The most important active cell transport mechanism is the sodium pump, which extrudes Na^+ from inside the cell in exchange for K^+ from outside the cell.⁶ In the kidney, it is confined to the basolateral membrane. It derives energy from the enzymatic hydrolysis of ATP, hence its more precise description as $\text{Na}^+\text{K}^+\text{-ATPase}$. It exchanges 3Na^+ ions for 2K^+ ions, which makes it electrogenic

Physiologic and Pharmacologic Factors with Effects on Glomerular Hemodynamics

Figure 2.6 Physiologic and pharmacologic influences on glomerular hemodynamics. The overall effect on glomerular filtration rate (GFR) will depend on renal blood flow, net ultrafiltration pressure, and the ultrafiltration coefficient (K_f), which is controlled by mesangial cell contraction and relaxation. The effects shown are those seen when the agents are applied (or inhibited) in isolation; the actual changes that occur are dose-dependent and are modulated by other agents. *In clinical practice, GFR is usually either decreased or unaffected. ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

because it extrudes a net positive charge from the cell. It is an example of a *primary* active transport mechanism. Other well-defined primary active transport mechanisms in the kidney are the proton-secreting H^+ -ATPase, important in H^+ secretion in the distal nephron, and Ca^{2+} -ATPase, partly responsible for calcium reabsorption.

Activity of the basolateral Na^+,K^+ -ATPase is key to the operation of all the passive transport processes outlined earlier. It ensures that the intracellular Na^+ concentration is kept low (10 to 20 mmol/l) and the K^+ concentration high (~150 mmol/l), compared with their extracellular concentrations (~140 and ~4 mmol/l, respectively). Sodium entry into tubular cells down the electrochemical gradient maintained by the sodium pump is either through Na^+ channels (in the distal nephron) or linked (coupled) through specific membrane carrier proteins to the influx (*cotransport*) or efflux (*countertransport*) of other molecules or ions. In various parts of the nephron, glucose, phosphate, amino acids, K^+ , and Cl^- can all be cotransported with Na^+ entry, whereas H^+ and Ca^{2+} can be countertransported against Na^+ entry. In each case the non-sodium molecule or ion is transported against its electrochemical gradient by use of energy derived from the “downhill” movement of sodium. Their ultimate dependence on the primary active sodium pump makes them *secondary* active transport mechanisms.

TRANSPORT IN SPECIFIC NEPHRON SEGMENTS

Given a typical GFR, approximately 180 l of largely protein-free plasma is filtered each day, necessitating massive reabsorption by the nephron as a whole. Figure 2.7 shows the major transport mechanisms operating along the nephron (with the exception of the loop of Henle, which is dealt with separately).

Proximal Tubule

The proximal tubule is adapted for bulk reabsorption. The epithelial cells have microvilli (brush border) on their apical surface, providing a large absorptive area; the basolateral membrane is thrown into folds that similarly enhance surface area. The cells are rich in mitochondria (concentrated near the basolateral membrane) and lysosomal vacuoles, and the tight junctions between adjacent cells are relatively leaky. The proximal convoluted tubule (PCT; *pars convoluta*) makes up the first two thirds of the proximal tubule; the final third is the proximal straight tubule (*pars recta*).

On the basis of subtle structural and functional differences, the proximal tubule epithelium is subdivided into three types: S_1 makes up the initial short segment of the PCT; S_2 , the remainder of the PCT and the cortical segment of the *pars recta*; and S_3 , the medullary segment of the *pars recta*. The proximal tubule as a whole is responsible for the bulk of Na^+ , K^+ , Cl^- , and HCO_3^- reabsorption, and almost complete reabsorption of glucose, amino acids, and low-molecular-weight proteins (e.g., retinol-binding protein, α - and β -microglobulins) that have penetrated the filtration barrier. Most other filtered solutes are also reabsorbed to some extent in the proximal tubule (e.g., ~60% of calcium, ~80% of phosphate, ~50% of urea). The proximal tubule is highly permeable to water, so no quantitatively significant osmotic gradient can be established; thus, most filtered water (~65%) is also reabsorbed at this site. In the final section of the proximal tubule (late S_2 and S_3), there is some secretion of weak organic acids and bases, including most diuretics and PAH.

Loop of Henle

The loop of Henle is defined anatomically as comprising the *pars recta* of the proximal tubule (thick descending limb), the thin descending and ascending limbs (thin ascending limbs are present only in long-looped nephrons; see later), the thick ascending limb (TAL), and the macula densa. In addition to its role in the continuing reabsorption of solutes (Na^+ , Cl^- , K^+ , Ca^{2+} , Mg^{2+} [the TAL normally reabsorbs the bulk of filtered Mg^{2+}]), this part of the nephron is responsible for the kidney's ability to generate a concentrated or dilute urine and is discussed in detail later.

Distal Nephron

The distal tubule is made up of three segments: the distal convoluted tubule (DCT), where thiazide-sensitive $NaCl$ reabsorption (through an apical cotransporter) occurs (see Fig. 2.7); the connecting tubule (CNT), whose function is essentially intermediate between that of the DCT and that of the next segment; and the initial collecting duct, which is of the same epithelial type as the cortical collecting duct. Two cell types make up the cortical collecting duct. The predominant type, the *principal cell* (see Fig. 2.7), is responsible for Na^+ reabsorption and K^+ secretion (as well as for water reabsorption; see later discussion). Sodium ions enter principal cells from the lumen through apical Na^+ channels (ENaC) and are extruded by the basolateral Na^+,K^+ -ATPase. This process is electrogenic and sets up a lumen-negative potential difference. Potassium ions enter principal cells through the same basolateral Na^+,K^+ -ATPase and leave through K^+ channels in both membranes; however, the smaller potential difference across the apical membrane (due to Na^+ entry) favors K^+ secretion into the lumen. The other cells in the late distal tubule and cortical collecting duct, the *intercalated cells*, are responsible for secretion of H^+ (by α -intercalated cells) or HCO_3^- (by β -intercalated cells) into the final urine (see Fig. 2.7). In the medullary collecting duct, there is a gradual transition in the epithelium. There are fewer and fewer intercalated cells while the “principal cells” are modified; although they reabsorb Na^+ , they have no apical K^+ channels and therefore do not secrete K^+ .

Figures 2.8 and 2.9 show the sites of Na^+ and K^+ reabsorption and secretion along the nephron. Figure 2.10 shows the pathophysiological consequences of known genetic defects in some of the major transporters in the nephron (see Chapter 47 for a detailed account).

GLOMERULOTUBULAR BALANCE

Because the proportion of filtered sodium that is excreted in the urine is so small (normally <1%), it follows that without a compensatory change in reabsorption, even small changes in the filtered load would cause major changes in the amount excreted. For example, if GFR were to increase by 10% and the rate of reabsorption remained unchanged, sodium excretion would increase more than 10-fold. However, an intrinsic feature of tubular function is that the extent of sodium reabsorption in a given nephron segment is roughly proportional to the sodium delivery to that segment. This is the phenomenon of *glomerulotubular balance*. Perfect glomerulotubular balance would mean that both sodium reabsorption and sodium excretion change in exactly the same proportion as the change in GFR; but in reality, glomerulotubular balance is usually less than perfect. Most studies of glomerulotubular balance have focused on the proximal tubule. However, succeeding nephron segments exhibit the

Figure 2.7 Major transport mechanisms along the nephron. Major transport proteins for solutes in the apical and basolateral membranes of tubular cells in specific regions of the nephron. Stoichiometry is not indicated; it is not 1:1 in all cases. *Red circles* represent primary active transport; *white circles* represent carrier-mediated transport (secondary active); *cylinders* represent ion channels. In the proximal convoluted tubule (PCT), Na^+ enters the cell through a $\text{Na}^+\text{-H}^+$ exchanger and a series of cotransporters; in the distal convoluted tubule (DCT), Na^+ enters the cell through the thiazide-sensitive $\text{Na}^+\text{-Cl}^-$ cotransporter; and in the principal cells of the cortical collecting duct (CCD), Na^+ enters through a channel (ENaC). In all cases, Na^+ is extruded from the cells through the basolateral $\text{Na}^+\text{,K}^+\text{-ATPase}$. Transporters in the thick ascending limb of Henle are dealt with separately (see Fig. 2.12).

same property, so if the load to the loop of Henle or to the distal tubule is increased, some of the excess is mopped up. This is part of the reason that diuretics acting on the proximal tubule are relatively ineffective compared with those acting farther along the nephron; with the latter, there is less scope for buffering of their effects downstream. It is also the reason that combining two diuretics acting at different nephron sites causes a more striking diuresis and natriuresis.

The mechanism of glomerulotubular balance is not fully understood. As far as the proximal tubule is concerned, physical factors operating across peritubular capillary walls may be

involved. Glomerular filtration of essentially protein-free fluid means that the plasma leaving the glomeruli in efferent arterioles and supplying the peritubular capillaries has a relatively high oncotic pressure, which favors uptake of fluid reabsorbed from the proximal tubules. If GFR were reduced in the absence of a change in RPF, peritubular capillary oncotic pressure would also be reduced and the tendency to take up fluid reabsorbed from the proximal tubule diminished. It is thought that some of this fluid might leak back through the leaky tight junctions, reducing net reabsorption (Fig. 2.11). However, this mechanism could work only if GFR changed in the absence of a corresponding change in

Figure 2.8 Renal sodium handling along the nephron. Figures outside the nephron represent the approximate percentage of the filtered load reabsorbed in each region. Figures within the nephron represent the percentages remaining. Most filtered sodium is reabsorbed in the proximal tubule and loop of Henle; normal day-to-day control of sodium excretion is exerted in the distal nephron.

Figure 2.9 Renal potassium handling along the nephron. Figures are not given for percentages reabsorbed or remaining in every region because quantitative information is incomplete, but most filtered potassium is reabsorbed in the proximal convoluted tubule and thick ascending limb of Henle; approximately 10% of the filtered load reaches the early distal tubule. Secretion by connecting tubule cells and principal cells in the late distal tubule–cortical collecting duct is variable and is the major determinant of potassium excretion.

Defects in Transport Proteins Resulting in Renal Disease	
Transporter	Consequence of Mutation
Proximal Tubule	
Apical Na ⁺ -cystine cotransporter	Cystinuria
Apical Na ⁺ -glucose cotransporter (SGLT2)	Renal glycosuria
Basolateral Na ⁺ -HCO ₃ ⁻ cotransporter	Proximal renal tubular acidosis
Intracellular H ⁺ -Cl ⁻ exchanger (ClC5)	Dent disease
Thick Ascending Limb	
Apical Na ⁺ -K ⁺ -2Cl ⁻ cotransporter	Bartter syndrome type 1
Apical K ⁺ channel	Bartter syndrome type 2
Basolateral Cl ⁻ channel	Bartter syndrome type 3
Basolateral Cl ⁻ channel accessory protein	Bartter syndrome type 4
Distal Convoluted Tubule	
Apical Na ⁺ -Cl ⁻ cotransporter	Gitelman's syndrome
Collecting Duct	
Apical Na ⁺ channel (principal cells)	Overexpression: Liddle's syndrome Underexpression: pseudohypoaldosteronism type 1b
Aquaporin-2 channel (principal cells)	Nephrogenic diabetes insipidus
Basolateral Cl ⁻ /HCO ₃ ⁻ exchanger (intercalated cells)	Distal renal tubular acidosis
Apical H ⁺ -ATPase (intercalated cells)	Distal renal tubular acidosis (with or without deafness)

Figure 2.10 Genetic defects in transport proteins resulting in renal disease. For more detailed coverage of these clinical conditions, see Chapter 47.

RPF; if the two change in parallel (i.e., unchanged *filtration fraction*), there would be no change in oncotic pressure.

A second contributory factor to glomerulotubular balance in the proximal tubule could be the filtered loads of glucose and amino acids; if their loads increase (because of increased GFR), the rates of sodium-coupled glucose and amino acid reabsorption in the proximal tubule will also increase. Finally, it has been proposed that the proximal tubular brush border microvilli serve a mechanosensor function, transmitting changes in torque (caused by altered tubular flow rates) to the cells' actin cytoskeleton, which can modulate tubular transporter activity appropriately (although the mechanisms are unknown).⁷

Although the renal sympathetic nerves and certain hormones can influence reabsorption in the proximal tubule and loop of Henle, the combined effects of autoregulation and glomerulotubular balance ensure that a relatively constant load of glomerular filtrate is delivered to the distal tubule under normal circumstances. It is in the final segments of the nephron that normal day-to-day control of sodium excretion is exerted. Evidence points toward important roles for the late DCT and the CNT, in addition to the collecting duct.⁸ *Aldosterone*, secreted from the adrenal cortex, stimulates mineralocorticoid receptors within principal cells and CNT cells, which leads to generation of the

Figure 2.11 Physical factors and proximal tubular reabsorption. Influence of peritubular capillary oncotic pressure on net reabsorption in proximal tubules. Uptake of reabsorbate into peritubular capillaries is determined by the balance of hydrostatic and oncotic pressures across the capillary wall. Compared with those in systemic capillaries, the peritubular capillary hydrostatic (P_{pc}) and oncotic (π_{pc}) pressures are low and high, respectively, so that uptake of proximal tubular reabsorbate into the capillaries is favored. If peritubular capillary oncotic pressure decreases (or hydrostatic pressure increases), less fluid is taken up, interstitial pressure increases, and more fluid may leak back into the lumen paracellularly; net reabsorption in proximal tubules would therefore be reduced.

regulatory protein *serum- and glucocorticoid-inducible kinase* (Sgk1), which increases the number of Na⁺ channels (ENaC) in the apical membrane (see Fig. 2.7). This stimulates Na⁺ uptake and further depolarizes the apical membrane, thereby facilitating K⁺ secretion in the late distal tubule and cortical collecting duct. Aldosterone also stimulates Na⁺ reabsorption and K⁺ secretion by upregulating the basolateral Na⁺,K⁺-ATPase.

The mineralocorticoid receptors have equal affinity *in vitro* for aldosterone and adrenal glucocorticoids. The circulating concentrations of adrenal glucocorticoids vastly exceed those of aldosterone, but *in vivo*, the mineralocorticoid receptors show specificity for aldosterone because of the presence along the distal nephron of the enzyme *11 β -hydroxysteroid dehydrogenase 2*, which inactivates glucocorticoids in the vicinity of the receptor.⁹

COUNTERCURRENT SYSTEM

A major function of the loop of Henle is the generation and maintenance of the interstitial osmotic gradient that increases from the renal cortex (~290 mOsm/kg) to the tip of the medulla (~1200 mOsm/kg). As indicated in Chapter 1, the loops of Henle of most superficial nephrons turn at the junction between the

outer and inner medulla, whereas those of deep nephrons (long-looped nephrons) penetrate the inner medulla to varying degrees. The anatomic loops of Henle reabsorb approximately 40% of filtered Na^+ (mostly in the pars recta and TAL) and approximately 25% of filtered water (in the pars recta and in the thin descending limbs of deep nephrons). (Recent evidence suggests that the thin

Figure 2.12 Transport mechanisms in the thick ascending limb of Henle. The major cellular entry mechanism is the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter. The transepithelial potential difference drives paracellular transport of Na^+ , K^+ , Ca^{2+} , and Mg^{2+} .

descending limb of superficial nephrons is relatively impermeable to water.¹⁰) Both the thin ascending limb (found only in deep nephrons) and the TAL are essentially impermeable to water; however, Na^+ is reabsorbed—passively in the thin ascending limb but actively in the TAL. Active Na^+ reabsorption in the TAL is again driven by the basolateral sodium pump, which maintains a low intracellular Na^+ concentration, allowing Na^+ entry from the lumen through the $\text{Na}^+\text{-2Cl}^-\text{-K}^+$ cotransporter (NKCC-2) and, to a much lesser extent, the $\text{Na}^+\text{-H}^+$ exchanger (Fig. 2.12). The apical NKCC-2 is unique to this nephron segment and is the site of action of loop diuretics like furosemide and bumetanide. Na^+ exits the cell through the sodium pump, and Cl^- and K^+ exit through basolateral ion channels and a $\text{K}^+\text{-Cl}^-$ cotransporter. K^+ also re-enters the lumen (recycles) through apical membrane potassium channels. Re-entry of K^+ into the tubular lumen is necessary for normal operation of the $\text{Na}^+\text{-2Cl}^-\text{-K}^+$ cotransporter, presumably because the availability of K^+ is a limiting factor for the transporter (the K^+ concentration in tubular fluid being much lower than that of Na^+ and Cl^-). K^+ recycling is also partly responsible for generating the lumen-positive potential difference found in this segment. This potential difference drives additional Na^+ reabsorption through the paracellular pathway; for each Na^+ reabsorbed transcellularly, another one is reabsorbed paracellularly (see Fig. 2.12).¹¹ Other cations (K^+ , Ca^{2+} , Mg^{2+}) are also reabsorbed by this route. The reabsorption of NaCl along the TAL in the absence of significant water reabsorption means that the tubular fluid leaving this segment is hypotonic; hence the name *diluting segment*.

The U-shaped, countercurrent arrangement of the loop of Henle, the differences in permeability of the descending and ascending limbs to Na^+ and water, and active Na^+ reabsorption in the TAL are the basis of *countercurrent multiplication* and generation of the medullary osmotic gradient (Fig. 2.13). Fluid

Figure 2.13 Countercurrent multiplication by the loop of Henle. The nephron drawn represents a deep (long-looped) nephron. Figures represent approximate osmolalities (mOsm/kg). Osmotic equilibration occurs in the thin descending limb, whereas NaCl is reabsorbed in the water-impermeable ascending limb; hypotonic fluid is delivered to the distal tubule. In the absence of vasopressin, this fluid remains hypotonic during its passage through the distal tubule and collecting duct, despite the large osmotic gradient favoring water reabsorption. A large volume of dilute urine is therefore formed. During maximal vasopressin secretion, water is reabsorbed down the osmotic gradient, so that tubular fluid becomes isotonic in the cortical collecting duct and hypertonic in the medullary collecting duct. A small volume of concentrated urine is formed.

entering the descending limb from the proximal tubule is isotonic (~290 mOsm/kg). On encountering the hypertonicity of the medullary interstitial fluid (which results from NaCl reabsorption in the water-impermeable ascending limb), the fluid in the descending limb comes into osmotic equilibrium with its surroundings, either by solute entry into the descending limb (superficial nephrons) or by water exit by osmosis (deep nephrons). These events, combined with continuing NaCl reabsorption in the ascending limb, result in a progressive increase in medullary osmolality from corticomedullary junction to papillary tip. A similar osmotic gradient exists in the thin descending limb, whereas at any level in the ascending limb, the osmolality is less than in the surrounding tissue. Thus, hypotonic (~100 mOsm/kg) fluid is delivered to the distal tubule. Ultimately, the energy source for countercurrent multiplication is active Na⁺ reabsorption in the TAL. As indicated, Na⁺ reabsorption in the thin ascending limb is passive, but how this comes about is not yet understood (see later discussion).

Role of Urea

The thin limbs of the loop of Henle are relatively permeable to urea (ascending > descending), but more distal nephron segments (TAL and beyond) are urea impermeable up to the final section of the inner medullary collecting duct. By this stage, vasopressin-dependent water reabsorption in the collecting ducts (see later discussion) has led to a high urea concentration within the lumen. Owing to vasopressin-sensitive urea transporters (UT-A1 and UT-A3) along the terminal segment of the inner medullary collecting duct, urea is reabsorbed (passively) into the inner medullary interstitium.¹² The interstitial urea exchanges with vasa recta capillaries (see later discussion), and some urea enters the S₃ segment of the pars recta and the descending and ascending thin limbs of the loop of Henle; it is then returned to the inner medullary collecting ducts to be reabsorbed. The net result of this urea recycling process is to add urea to the inner medullary interstitium, thereby increasing interstitial osmolality. The fact that the high urea concentration within the medullary collecting duct is balanced by a similarly high urea concentration in the medullary interstitium allows large quantities of urea to be excreted without incurring the penalty of an osmotic diuresis, as the urea in the collecting duct is rendered osmotically ineffective. Moreover, the high urea concentration in the medullary interstitium should also increase osmotic water abstraction from the thin descending limbs of deep nephrons, raising the intraluminal Na⁺ concentration within the thin descending limbs. Until recently, it was thought that this process set the scene for passive Na⁺ reabsorption from the thin ascending limbs. However, mice with genetic deletion of the urea transporters UT-A1 and UT-A3 have a much reduced urea concentration in the inner medullary interstitium but a normal interstitial NaCl gradient.¹² Thus, the mechanisms responsible for the inner medullary electrolyte gradient are still unclear. However, the ultimate driving force for countercurrent multiplication is active Na⁺ reabsorption in the TAL, a fact underlined by the disruption of the osmotic gradient when loop diuretics are given.

Vasa Recta

The capillaries that supply the medulla also have a special anatomic arrangement. If they passed through the medulla as a more usual capillary network, they would soon dissipate the medullary osmotic gradient because of equilibration of the hypertonic

Figure 2.14 Countercurrent exchange by the vasa recta. Figures represent approximate osmolalities (mOsm/kg). The vasa recta capillary walls are highly permeable, but the U-shaped arrangement of the vessels minimizes the dissipation of the medullary osmotic gradient. Nevertheless, because equilibration across the capillary walls is not instantaneous, a certain amount of solute is removed from the interstitium.

interstitium with the isotonic capillary blood. This does not happen to any appreciable extent because the U-shaped arrangement of the *vasa recta* ensures that solute entry and water loss in the descending vasa recta are offset by solute loss and water entry in the ascending vasa recta. This is the process of *countercurrent exchange* and is entirely passive (Fig. 2.14).

Renal Medullary Hypoxia

Countercurrent exchange by the medullary capillaries applies also to oxygen, which diffuses from descending to ascending vasa recta, bypassing the deeper regions. This phenomenon, combined with ongoing energy-dependent salt transport in the outer medullary TAL, has the consequence that medullary tissue is relatively hypoxic. Thus, the partial pressure of oxygen normally decreases from ~50 mm Hg in the cortex to ~10 mm Hg in the inner medulla.¹³ Administration of furosemide, which inhibits oxygen consumption in the TAL, increases medullary oxygenation. As part of the adaptation to this relatively hypoxic environment, medullary cells have a higher capacity for glycolysis than do cells in the cortex. Moreover, a number of *heat shock proteins*, which assist cell survival by restoring damaged proteins and by inhibiting apoptosis, are expressed in the medulla.¹³

The degree of medullary hypoxia depends on the balance between medullary blood flow and oxygen consumption in the TAL. The medullary blood flow is controlled by contractile cells called *pericytes*, which are attached to the descending vasa recta. In health, this balance is modulated by a variety of autocrine and paracrine agents (e.g., nitric oxide, eicosanoids, adenosine; see later discussion), several of which can increase medullary oxygenation by simultaneously reducing pericyte contraction and TAL transport. There is evidence that some cases of radio-contrast-induced nephropathy result from a disturbance of the balance between oxygen supply and demand, with consequent hypoxic medullary injury in which the normal cellular

adaptations are overwhelmed, with subsequent apoptotic and necrotic cell death.

VASOPRESSIN (ANTIDIURETIC HORMONE) AND WATER REABSORPTION

Vasopressin, or antidiuretic hormone, is a nonapeptide synthesized in specialized neurons of the supraoptic and paraventricular nuclei. It is transported from these nuclei to the posterior pituitary and released in response to increases in plasma osmolality and decreases in blood pressure. Osmoreceptors are found in the hypothalamus, and there is also input to this region from arterial baroreceptors and atrial stretch receptors. The actions of vasopressin are mediated by three receptor subtypes: V_{1a} , V_{1b} , and V_2 receptors. V_{1a} receptors are found in vascular smooth muscle and are coupled to the phosphoinositol pathway; they cause an increase in intracellular Ca^{2+} , resulting in contraction. V_{1a} receptors have also been identified in the apical membrane of several nephron segments, although their role is not yet clear. V_{1b} receptors are found in the anterior pituitary, where vasopressin modulates adrenocorticotrophic hormone release. V_2 receptors are found in the basolateral membrane of principal cells in the late distal tubule and the whole length of the collecting duct; they are coupled by a G_s protein to cyclic adenosine monophosphate generation, which ultimately leads to the insertion of water channels (aquaporins) into the apical membrane of this otherwise water-impermeable segment (Fig. 2.15). In the X-linked form of nephrogenic diabetes insipidus (the most common hereditary cause), the V_2 receptor is defective.¹⁴

Several aquaporins have been identified in the kidney.¹⁵ Aquaporin 1 is found in apical and basolateral membranes of all proximal tubules and of thin descending limbs of long-looped

nephrons; it is largely responsible for the permanently high water permeability of these segments. Aquaporin 3 is constitutively expressed in the basolateral membrane of CNT cells and cortical and outer medullary principal cells, and aquaporin 4 is constitutively expressed in the basolateral membrane of outer medullary principal cells and inner medullary collecting duct cells; but it is aquaporin 2 that is responsible for the variable water permeability of the late distal tubule and collecting duct. Acute vasopressin release causes shuttling of aquaporin 2 from intracellular vesicles to the apical membrane, while chronically raised vasopressin levels increase aquaporin 2 expression. The apical insertion of aquaporin 2 allows reabsorption of water, driven by the high interstitial osmolality achieved and maintained by the counter-current system. Vasopressin also contributes to the effectiveness of this system by stimulating Na^+ reabsorption in the TAL (although this effect may be functionally significant only in rodents¹⁶) and urea reabsorption through the UT-A1 and UT-A3 transporters in the inner medullary collecting duct. In the rare autosomal recessive and even rarer autosomal dominant forms of nephrogenic diabetes insipidus, aquaporin 2 is abnormal or fails to translocate to the apical membrane.¹⁵

Aquaporin 2 dysfunction also appears to underlie the well-known urinary concentrating defect associated with hypercalcaemia. Increased intraluminal Ca^{2+} concentrations, acting through an apically located calcium-sensing receptor, interfere with the insertion of aquaporin 2 channels in the apical membrane of the medullary collecting duct.¹⁷ In addition, stimulation of a calcium receptor in the basolateral membrane of the TAL inhibits solute transport in this nephron segment (through inhibition of the apical NKCC-2 and potassium channels), thereby reducing the medullary osmotic gradient.¹⁸

INTEGRATED CONTROL OF RENAL FUNCTION

One of the major functions of the kidneys is the regulation of blood volume, through the regulation of *effective circulating volume*, an unmeasurable, conceptual volume that reflects the degree of fullness of the vasculature. This is achieved largely by control of the sodium content of the body. The mechanisms involved in the regulation of effective circulating volume are discussed in detail in Chapter 7. Some of the more important mediator systems are introduced here.

Renal Interstitial Hydrostatic Pressure and Nitric Oxide

Acute increases in arterial blood pressure lead to natriuresis (*pressure natriuresis*). Because autoregulation is not perfect, part of this response is mediated by increases in RBF and GFR (see Fig. 2.3), but the main cause is reduced tubular reabsorption, which appears to result largely from an increase in *renal interstitial hydrostatic pressure* (RIHP). An elevated RIHP could reduce net reabsorption in the proximal tubule by increasing paracellular backflux through the tight junctions of the tubular wall (see Fig. 2.11). The increase in RIHP is thought to be dependent on intrarenally produced *nitric oxide*.¹⁹ Moreover, increased nitric oxide production in macula densa cells (which contain the neuronal [type I] isoform of nitric oxide synthase [nNOS]) blunts the sensitivity of TGF, thereby allowing increased $NaCl$ delivery to the distal nephron without incurring a TGF-mediated decrease in GFR.²⁰

Another renal action of nitric oxide results from the presence of inducible (type II) nitric oxide synthase in glomerular

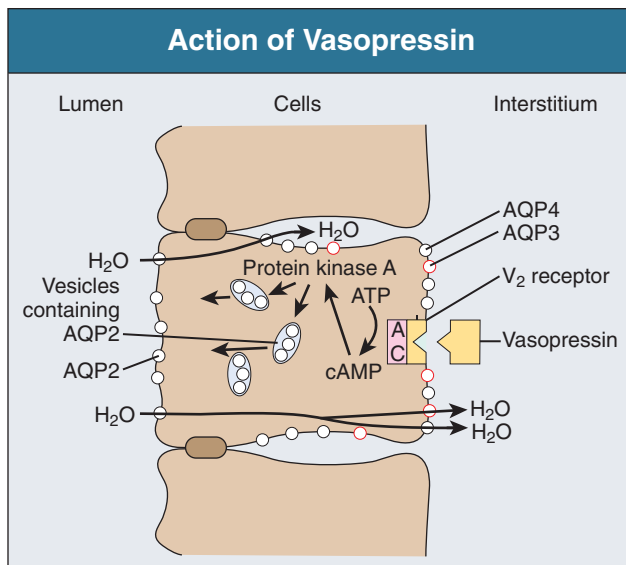

Figure 2.15 Mechanism of action of vasopressin (antidiuretic hormone). The hormone binds to V_2 receptors on the basolateral membrane of collecting duct principal cells and increases intracellular cyclic adenosine monophosphate (cAMP) production, causing, through intermediate reactions involving protein kinase A, insertion of preformed water channels (aquaporin 2 [AQP2]) into the apical membrane. The water permeability of the basolateral membrane, which contains aquaporins 3 and 4, is permanently high. Therefore, vasopressin secretion allows transcellular movement of water from lumen to interstitium. AC, adenylate cyclase.

mesangial cells: local production of nitric oxide counteracts the mesangial contractile response to agonists such as Ang II and endothelin (see later discussion). Furthermore, nitric oxide may have a role in the regulation of medullary blood flow. Locally synthesized nitric oxide offsets the vasoconstrictor effects of other agents on the pericytes of the descending vasa recta, and it reduces Na^+ reabsorption in the TAL; both actions will help protect the renal medulla from hypoxia. Finally, nitric oxide may promote natriuresis and diuresis through direct actions on the renal tubule. Thus, in addition to its effect on the TAL, locally produced nitric oxide inhibits Na^+ and water reabsorption in the collecting duct.²¹

Renal Sympathetic Nerves

Reductions in arterial pressure or central venous pressure result in reduced afferent signaling from arterial baroreceptors or atrial volume receptors, which elicits a reflex increase in renal sympathetic nervous discharge. This reduces urinary sodium excretion in at least three ways:

- Constriction of afferent and efferent arterioles (predominantly afferent), thereby directly reducing RBF and GFR, and indirectly reducing RIHP.
- Direct stimulation of sodium reabsorption in the proximal tubule and the TAL of the loop of Henle.
- Stimulation of *renin* secretion by afferent arteriolar cells (see later discussion).

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) is central to the control of extracellular fluid volume (ECFV) and blood pressure. Renin is synthesized and stored in specialized afferent arteriolar cells that form part of the juxtaglomerular apparatus (see Fig. 2.4) and is released into the circulation in response to

- Increased renal sympathetic nervous discharge.
- Reduced stretch of the afferent arteriole after a reduction in renal perfusion pressure.
- Reduced delivery of NaCl to the macula densa region of the nephron.

Renin catalyzes the production of the decapeptide angiotensin I from circulating angiotensinogen (synthesized in the liver); angiotensin I is in turn converted to the octapeptide *Ang II* by the ubiquitous angiotensin-converting enzyme. *Ang II* has a number of actions pertinent to the control of ECFV and blood pressure:

- It causes general arteriolar vasoconstriction, including renal afferent and (particularly) efferent arterioles, thereby increasing arterial pressure but reducing RBF. The tendency of P_{gc} to increase is offset by Ang II-induced mesangial cell contraction and reduced K_f ; thus, the overall effect on GFR is unpredictable.
- It directly stimulates sodium reabsorption in the proximal tubule.
- It stimulates aldosterone secretion from the zona glomerulosa of the adrenal cortex. As described earlier, aldosterone stimulates sodium reabsorption in the distal tubule and collecting duct.

Eicosanoids

Eicosanoids are a family of metabolites of arachidonic acid produced enzymatically by three systems: cyclooxygenase (of which

two isoforms exist, COX-1 and COX-2, both expressed in the kidney), cytochrome P-450, and lipoxygenase. The major renal eicosanoids produced by the COX system are *prostaglandin E₂* and *prostaglandin I₂*, both of which are renal vasodilators and act to buffer the effects of renal vasoconstrictor agents such as Ang II and norepinephrine; and *thromboxane A₂*, a vasoconstrictor. Under normal circumstances, prostaglandins *E₂* and *I₂* have little effect on renal hemodynamics; but during stressful situations such as hypovolemia, they help protect the kidney from excessive functional changes. Consequently, nonsteroidal anti-inflammatory drugs (NSAIDs), which are COX inhibitors, can cause dramatic falls in GFR. Prostaglandin *E₂* also has tubular effects, inhibiting Na^+ reabsorption in the TAL of the loop of Henle and both Na^+ and water reabsorption in the collecting duct.²² Its action in the TAL, together with a dilator effect on vasa recta pericytes, is another paracrine regulatory mechanism that helps protect the renal medulla from hypoxia. This may explain why inhibition of COX-2 can reduce medullary blood flow and cause apoptosis of medullary interstitial cells.

The metabolism of arachidonic acid by renal cytochrome P-450 enzymes yields *epoxyeicosatrienoic acids* (EETs), *20-hydroxyeicosatetraenoic acid* (20-HETE), and *dihydroxyeicosatrienoic acids* (DHETs). These compounds appear to have a multiplicity of autocrine, paracrine, and second-messenger effects on the renal vasculature and tubules that have not yet been fully unraveled.²³ Like prostaglandins, EETs are vasodilator agents, whereas 20-HETE is a potent renal arteriolar constrictor and may be involved in the vasoconstrictor effect of Ang II as well as the TGF mechanism. 20-HETE also constricts vasa recta pericytes and may be involved in the control of medullary blood flow. Some evidence suggests that locally produced 20-HETE and EETs can inhibit sodium reabsorption in the proximal tubule and TAL.²⁴ Indeed, cytochrome P-450 metabolites of arachidonic acid may contribute to the reduced proximal tubular reabsorption seen in pressure natriuresis.

The third enzyme system that metabolizes arachidonic acid, the lipoxygenase system, is activated (in leukocytes, mast cells, and macrophages) during inflammation and injury and is not considered here.

COX-2 is present in macula densa cells and has a critical role in the release of renin from juxtaglomerular cells in response to reduced NaCl delivery to the macula densa.²² A low-sodium diet increases COX-2 expression in the macula densa and simultaneously increases renin secretion; the renin response is virtually abolished in COX-2 knockout mice or during pharmacologic inhibition of COX-2. It is likely, therefore, that the hyporeninemia observed during administration of NSAIDs is largely a consequence of COX-2 inhibition. As well as COX-2, the enzyme prostaglandin *E* synthase is expressed in macula densa cells, and it is thought that the principal COX-2 product responsible for enhancing renin secretion is prostaglandin *E₂*, acting on specific receptors that have been identified in juxtaglomerular cells; it is not clear whether prostaglandin *I₂* is also synthesized in macula densa cells. As already indicated, nNOS (type I) is also present in macula densa cells and produces nitric oxide that blunts TGF.²⁵ Nitric oxide also has a permissive role in renin secretion, although the mechanism is not understood. The increase in macula densa COX-2 expression induced by a low-sodium diet is attenuated during administration of selective nNOS inhibitors, which has led to speculation that nitric oxide is responsible for the increase in COX-2 activity and the resulting increase in juxtaglomerular renin secretion.²⁶ The established and proposed roles of COX-2 and

Figure 2.16 Interactions between macula densa and afferent arteriole: proposed mediators of renin secretion and tubuloglomerular feedback. Both cyclooxygenase 2 (COX-2) and neuronal nitric oxide synthase (nNOS) enzyme systems are present in macula densa cells. Increased NaCl delivery to the macula densa stimulates NaCl entry into the cells through the Na⁺-K⁺-2Cl⁻ cotransporter. This causes afferent arteriolar constriction through adenosine or adenosine triphosphate (ATP), and also inhibits COX-2 activity; the latter effect might be mediated partly through inhibition of (nNOS-mediated) nitric oxide (NO) production. Generation of prostaglandin E₂ by COX-2 stimulates renin release. Prostaglandin E₂ (PGE₂) also modulates vasoconstriction, as does nitric oxide.

nNOS in the macula densa are shown diagrammatically in Figure 2.16.

Atrial Natriuretic Peptide

If blood volume increases significantly, the resulting atrial stretch stimulates the release of *atrial natriuretic peptide* from atrial myocytes. This hormone increases sodium excretion, partly by suppression of renin and aldosterone release and partly by a direct inhibitory effect on sodium reabsorption in the medullary collecting duct. Atrial natriuretic peptide may additionally increase GFR because high doses cause afferent arteriolar vasodilation and mesangial cell relaxation (thus increasing K_f ; see Fig. 2.6).

Endothelins

Endothelins are potent vasoconstrictor peptides to which the renal vasculature is exquisitely sensitive.²⁷ They function primarily as autocrine or paracrine agents. The kidney is a rich source of endothelins, the predominant isoform being endothelin 1 (ET-1). ET-1 is generated throughout the renal vasculature, including afferent and efferent arterioles (where it causes vasoconstriction, possibly mediated by 20-HETE) and mesangial cells (where it causes contraction, i.e., decreases K_f). Consequently, renal ET-1 can cause profound reductions in RBF and GFR (Fig. 2.6).

In contrast to its effect on GFR, it is now clear that ET-1 can act on the renal tubule to increase urinary Na⁺ and water

excretion. ET-1 levels are highest in the renal medulla—in the TAL and, more prominently, the inner medullary collecting duct. The distribution of renal endothelin receptors (ET_A and ET_B receptors) reflects the sites of production; the predominant receptor in the inner medulla is ET_B.²⁸ Mice with collecting duct-specific deletions of either ET-1 or ET_B receptors exhibit salt-sensitive hypertension, whereas collecting duct-specific ET_A receptor deletion results in no obvious renal phenotype.²¹ ET-1 knockout mice also show a greater sensitivity to vasopressin than do wild-type mice. There is mounting evidence that the natriuretic and diuretic effects of medullary ET_B receptor stimulation are mediated by nitric oxide.²¹ Taken together with evidence that ET-1 can inhibit Na⁺ reabsorption in the medullary TAL (also likely to be mediated by nitric oxide), these findings highlight the potential importance of ET-1 and nitric oxide interactions in the control of Na⁺ and water excretion.

Purines

There is increasing evidence that extracellular *purines* (e.g., ATP, adenosine diphosphate [ADP], adenosine, uric acid) can act as autocrine or paracrine agents within the kidneys. Purinoceptors are subdivided into P1 and P2 receptors. The P1 receptors are responsive to adenosine and are more usually known as adenosine receptors (A₁, A_{2a}, A_{2b}, and A₃); the P2 receptors, responsive to nucleotides (e.g., ATP and ADP), are further subdivided into P2X (ligand-gated ion channels) and P2Y (metabotropic) receptors, each category having a number of subtypes. As indicated earlier, A₁ and P2X₁ receptors are found in afferent arterioles and mediate vasoconstriction. Purinoceptors are also found in the apical and basolateral membranes of renal tubular cells. Stimulation of A₁ receptors enhances proximal tubular reabsorption and inhibits collecting duct Na⁺ reabsorption, whereas stimulation of P2 receptors generally has an inhibitory effect on tubular transport.²⁹ Thus, luminally applied nucleotides, acting on a variety of P2 receptor subtypes, can inhibit Na⁺ reabsorption in the proximal tubule, distal tubule, and collecting duct³⁰; and stimulation of P2Y₂ receptors in the collecting duct inhibits vasopressin-sensitive water reabsorption; an observation reinforced by the report of increased concentrating ability in P2Y₂ receptor knockout mice.³¹ Despite these clear indications of tubular effects of nucleotides, further studies will be necessary before their roles in normal tubular physiology are clarified.

Finally, there is some evidence that the end product of purine metabolism, uric acid, may cause renal vasoconstriction, possibly by inhibiting endothelial release of nitric oxide and stimulation of renin.³²

Assessment of Renal Function

Lesley A. Stevens, Shani Shastri, Andrew S. Levey

GLOMERULAR FILTRATION RATE

Glomerular filtration rate (GFR) is a product of the average filtration rate of each single nephron, the filtering unit of the kidneys, multiplied by the number of nephrons in both kidneys. The normal level for GFR is approximately 130 ml/min per 1.73 m² for men and 120 ml/min per 1.73 m² for women, with considerable variation among individuals according to age, sex, body size, physical activity, diet, pharmacologic therapy, and physiologic states such as pregnancy.¹ To standardize the function of the kidney for differences in kidney size, which is proportional to body size, GFR is adjusted for body surface area, computed from height and weight, and is expressed per 1.73 m² surface area, the mean surface area of young men and women. Even after adjustment for body surface area, GFR is approximately 8% higher in young men than in women and declines with age; the mean rate of decline is approximately 0.75 ml/min per year after the age of 40 years, but the variation is wide and the sources of variation are poorly understood. During pregnancy, GFR increases by about 50% in the first trimester and returns to normal immediately after delivery. GFR has a diurnal variation and is 10% lower at midnight compared with the afternoon. Within an individual, GFR is relatively constant over time but varies considerably among people, even after adjustment for the known variables.

Reductions in GFR can be due to either a decline in the nephron number or a decline in the single-nephron GFR (SNGFR) from physiologic or hemodynamic alterations. An increase in SNGFR due to increased glomerular capillary pressure or glomerular hypertrophy can compensate for a decrease in nephron number, and, therefore, the level of GFR may not reflect the loss of nephrons. As a result, there may be substantial kidney damage before GFR decreases.

MEASUREMENT OF THE GLOMERULAR FILTRATION RATE

GFR cannot be measured directly. Instead, it is measured as the urinary clearance of an ideal filtration marker.

Concept of Clearance

Clearance of a substance is defined as the volume of plasma cleared of a marker by excretion per unit of time. The clearance of substance x (C_x) can be calculated as $C_x = A_x/P_x$, where A_x is the amount of x eliminated from the plasma, P_x is the average

plasma concentration, and C_x is expressed in units of volume per time. Clearance does not represent an actual volume; rather, it is a virtual volume of plasma that is completely cleared of the substance per unit of time. The value for clearance is related to the efficiency of elimination: the greater the rate of elimination, the higher the clearance. Clearance of substance x is the sum of the urinary and extrarenal clearance; for substances that are eliminated by renal and extrarenal routes, plasma clearance exceeds urinary clearance.

Urinary Clearance

The amount of substance x excreted in the urine can be calculated as the product of the urinary flow rate (V) and the urinary concentration (U_x). Therefore, urinary clearance is defined as follows:

$$C_x = (U_x \times V)/P_x$$

Urinary excretion of a substance depends on filtration, tubular secretion, and tubular reabsorption. Substances that are filtered but not secreted or reabsorbed by the tubules are ideal filtration markers because their urinary clearance can be used as a measure of GFR. For substances that are filtered and secreted, urinary clearance exceeds GFR; and for substances that are filtered and reabsorbed, urinary clearance is less than GFR.

Measurement of urinary clearance requires a timed urine collection for measurement of urine volume as well as urine and plasma concentrations of the filtration marker. Special care must be taken to avoid incomplete urine collections, which will limit the accuracy of the clearance calculation.

Plasma Clearance

There is an increasing interest in measurement of plasma clearance because it avoids the need for a timed urine collection. GFR is calculated from plasma clearance (C_x) after a bolus intravenous injection of an exogenous filtration marker, with the clearance (C_x) computed from the amount of the marker administered (A_x) divided by the plasma concentration (P_x), which is equivalent to the area under the curve of plasma concentration versus time.

$$C_x = A_x/P_x$$

The decline in plasma levels is secondary to the immediate disappearance of the marker from the plasma into its volume of distribution (fast component) and to renal excretion (slow

component). Plasma clearance is best estimated by use of a two-compartment model that requires blood sampling early (usually two or three time points until 60 minutes) and late (one to three time points from 120 minutes onward). Like urinary clearance, plasma clearance of a substance depends on filtration, tubular secretion, and tubular reabsorption and, in addition, extrarenal elimination.

Exogenous Filtration Markers

Inulin, a 5200-d uncharged polymer of fructose, was the first substance described as an ideal filtration marker and remains the gold standard against which other markers are evaluated. The classic protocol for inulin clearance requires a continuous intravenous infusion to achieve a steady state and bladder catheterization with multiple timed urine collections. Because this technique is cumbersome, and inulin measurement requires a difficult chemical assay, this method has not been used widely in clinical practice and remains a research tool. Alternative exogenous substances include iothalamate, iothexol, ethylenediaminetetraacetic acid, and diethylenetriaminepentaacetic acid, often chelated to radioisotopes for ease of detection (Fig. 3.1). Alternative protocols to assess clearance have also been validated, including subcutaneous injection and spontaneous bladder emptying. There are advantages to alternative exogenous filtration markers and methods, but also limitations. Understanding of the strengths and limitations of each alternative marker and each clearance method will facilitate interpretation of measured GFR.²

Exogenous Filtration Markers for Estimation of GFR		
Marker	Method of Administration	Comments
Inulin	Continuous IV	Gold standard
Iothalamate	Bolus IV or subcutaneous	Can be administered as radioactive compound with ¹²⁵ I as the tracer or in nonradioactive form, with assay using HPLC methods. In radioactive form, potential problem of thyroid uptake of ¹²⁵ I. Iothalamate is secreted, leading to overestimation of GFR
^{99m} Tc-DTPA	Bolus IV	Dissociation of ^{99m} Tc leads to plasma protein binding and underestimation of GFR
⁵¹ Cr-EDTA	Bolus IV	10% lower clearance than inulin
Iothexol	Bolus IV	Low incidence of adverse effects Comparable to inulin Expensive and difficult to perform assay

Figure 3.1 Exogenous filtration markers for estimation of glomerular filtration rate. ⁵¹Cr-EDTA, ⁵¹Cr-labeled ethylenediaminetetraacetic acid; GFR, glomerular filtration rate; ^{99m}Tc-DTPA, ^{99m}Tc-labeled diethylenetriaminepentaacetic acid.

Endogenous Filtration Markers

Creatinine is the most commonly used endogenous filtration marker in clinical practice. Urea was widely used in the past, and cystatin C presently shows great promise. A comparison of these markers is outlined in Figure 3.2. For filtration markers that are excreted in the urine, urinary clearance can be computed from a timed urine collection and a single measurement of serum concentration. If the serum level is not constant during the urine collection, as in acute kidney disease or when residual kidney function is assessed in dialysis patients, it is also necessary to obtain additional blood samples during the urine collection to estimate the average serum concentration.

Estimation of GFR from Plasma Levels of Endogenous Filtration Markers

Figure 3.3 shows the relationship of plasma concentration of substance x to its generation (G_x) by cells and dietary intake, urinary excretion ($U_x \times V$), and extrarenal elimination (E_x) by gut and liver. The plasma level is related to the reciprocal of the level of GFR, but it is also influenced by generation, tubular secretion and reabsorption, and extrarenal elimination, collectively termed non-GFR determinants of the plasma level.

In the steady state, a constant plasma level of substance x is maintained because generation is equal to urinary excretion and extrarenal elimination. Estimating equations incorporate demographic and clinical variables as surrogates for the non-GFR determinants and provide a more accurate estimate of GFR than the reciprocal of the plasma level alone. Estimating equations are derived from regression of measured GFR on measured values of the filtration marker and observed values of the demographic and clinical variables. Estimated GFR may differ from measured GFR in a patient if there is a discrepancy between the true and average values for the relationship of the surrogate to the non-GFR determinants of the filtration marker. Other sources of errors include measurement error in the filtration marker (including failure to calibrate the assay for the filtration marker to the assay used in the development of the equation), measurement error in GFR in development of the equation, and regression to the mean. In principle, all these errors are likely to be greater at higher values for GFR.

CREATININE

Creatinine Metabolism and Excretion

Creatinine is a 113-d end product of muscle catabolism.¹ Advantages of creatinine include its ease of measurement and the low cost and widespread availability of assays. Disadvantages include the large number of non-GFR determinants (see Fig. 3.2), leading to a wide range of GFR for a given plasma creatinine level. For example, a serum creatinine level of 1.5 mg/dl (132 μ mol/l) may correspond to a GFR from approximately 20 to 90 ml/min per 1.73 m².

Creatinine is derived by the metabolism of phosphocreatine in muscle as well as from dietary meat intake or creatine supplements. Creatinine generation is proportional to muscle mass, which can be estimated from age, gender, race, and body size. Figure 3.4 lists factors that can affect creatinine generation.

Creatinine is released into the circulation at a constant rate. It is not protein bound and is freely filtered across the glomerulus and secreted by the tubules. Several medications, such as cimetidine and trimethoprim, competitively inhibit creatinine

Comparison of Creatinine, Urea, and Cystatin C as Filtration Markers			
Variable	Creatinine	Urea	Cystatin C
Molecular properties			
Weight	113 daltons	60 daltons	13,000 daltons
Structure	Amino acid derivative	Organic molecular product of protein metabolism	Nonglycosylated basic protein
Physiologic determinants of serum level			
Generation	Varies, according to muscle mass and dietary protein; lower in elderly persons, women, and Caucasians	Varies, according to dietary protein intake and catabolism	Thought to be constant by all nucleated cells; variation in cystatin levels, independent of GFR, may be due to generation
Handling by the kidney	Filtered, secreted, and excreted in the urine	Filtered, reabsorbed, and excreted in the urine	Filtered, reabsorbed, and catabolized
Extrarenal elimination	Yes; increases at reduced GFR	Yes; increases at reduced GFR	Preliminary evidence of increases at reduced GFR
Use in estimating equations for GFR			
Demographic and clinical variables as surrogates for physiologic determinants	Age, sex, and race; related to muscle mass	Not applicable	Unknown
Accuracy	Accurate for GFR <60 ml/min/1.73 m ²	Not applicable	Unknown
Assay			
Method	Colorimetric or enzymatic	Direct measurement, enzymatic, colorimetric, and electrochemical	PENIA or PETIA
Assay precision	Very good except at low range	Precise throughout the range	Precise throughout the range
Clinical laboratory practice	Multiple assays; widely used nonstandard calibration	Multiple assays; enzymatic and colorimetric more commonly used	Not on most autoanalyzers; not standardized
Reference standard	IDMS	IDMS	None at present

GFR, glomerular filtration rate; IDMS, isotope dilution gas chromatography–mass spectroscopy; PENIA, particle-enhanced nephelometric immunoassay; PETIA, particle-enhanced turbidimetric immunoassay.

Figure 3.2 Comparison of creatinine, urea, and cystatin C as filtration markers. (Modified from reference 3.)

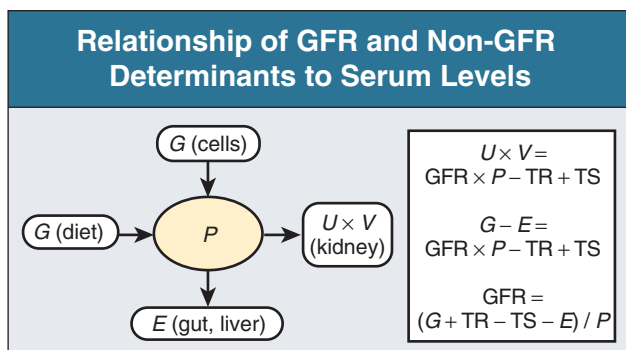

Figure 3.3 Relationship of GFR and non-GFR determinants to serum levels. G, generation; E, extrarenal elimination; TR, tubular reabsorption; TS, tubular secretion. (Modified with permission from reference 4.)

secretion and reduce creatinine clearance. These medications thus lead to a rise in the serum creatinine concentration without an effect on GFR (see Fig. 3.4).

In addition, creatinine is contained in intestinal secretions and can be degraded by bacteria. If GFR is reduced, the amount of creatinine eliminated through this extrarenal route is increased. Antibiotics can raise serum creatinine concentration by destroying intestinal flora, thereby interfering with extrarenal elimination, as well as by reduction of the GFR. The rise in serum creatinine concentration after inhibition of tubular secretion and extrarenal elimination is greater in patients with a reduced GFR. Clinically, it can be difficult to distinguish a rise in serum creatinine concentration due to inhibition of creatinine secretion or extrarenal elimination from a decline in GFR, but processes other than a decline in GFR should be suspected if serum urea concentration remains unchanged despite a significant change in serum creatinine concentration in a patient with an initially reduced GFR.

Factors Affecting Serum Creatinine Concentration		
	Effect on Serum Creatinine	Mechanism/Comment
Age	Decrease	Reduced creatinine generation due to age-related decline in muscle mass
Female sex	Decrease	Reduced creatinine generation due to reduced muscle mass
Race African American	Increase	Higher creatinine generation due to higher average muscle mass in African Americans; not known how muscle mass in other races compares with that of African Americans or Caucasians
Diet Vegetarian diet	Decrease	Decrease in creatinine generation
Ingestion of cooked meats and creatinine supplements	Increase	Transient increase in creatinine generation; however, this may be blunted by transient increase in GFR
Body habitus Muscular	Increase	Increased muscle generation due to increased muscle mass \pm increased protein intake
Malnutrition, muscle wasting, amputation	Decrease	Reduced creatinine generation due to reduced muscle mass \pm reduced protein intake
Obesity	No change	Excess mass is fat, not muscle mass, and does not contribute to increased creatinine generation
Medications Trimethoprim, cimetidine, fibric acid derivatives other than gemfibrozil	Increase	Reduced tubular secretion of creatinine
Keto acids, some cephalosporins	Increase	Interference with alkaline picrate assay for creatinine

Figure 3.4 Factors affecting serum creatinine concentration. (Reprinted with permission from reference 5.)

Creatinine clearance is usually computed from the creatinine excretion in a 24-hour urine collection and single measurement of serum creatinine in the steady state. In a complete collection, creatinine excretion should be approximately 20 to 25 mg/kg per day and 15 to 20 mg/kg per day in healthy young men and women, respectively, and deviations from these expected values can give some indication of errors in timing or completeness of urine collection. Creatinine clearance systematically overestimates GFR because of tubular creatinine secretion. In the past, the amount of creatinine excreted by tubular secretion at normal levels of GFR was thought to be relatively small (10% to 15%), but with newer, more accurate assays for low values of serum creatinine, it appears that this difference may be substantially greater. At low values of GFR, the amount of creatinine excreted by tubular secretion may exceed the amount filtered.⁶

Creatinine Assay

Historically, the most commonly used assay for measurement of serum creatinine was the alkaline picrate (Jaffe) assay that generates a color reaction. Chromogens other than creatinine are known to interfere with the assay, giving rise to errors of up to approximately 20% in normal subjects.⁴ Modern enzymatic assays do not detect non-creatinine chromogens and yield lower serum levels than with the alkaline picrate assays. Until recently, calibration of assays to adjust for this interference was not standardized across laboratories.

To address the heterogeneity in creatinine assays, the College of American Pathologists has prepared fresh-frozen serum pools with known creatinine levels that enable standardization of creatinine measurements and calibration of equipment.⁷ Until standardization is complete globally, the variability in the calibration of creatinine assays will remain an important limitation of the use of GFR estimating equations, especially at higher levels of estimated GFR. This will affect the ability to compare the level of kidney function based on serum creatinine concentration reported by different laboratories, especially when the estimated GFR is more than 60 ml/min per 1.73 m². Standardization will reduce, but not completely eliminate, the error at higher levels of GFR.

Formulae for Estimating the Glomerular Filtration Rate from Serum Creatinine

GFR can be estimated from serum creatinine by equations that use age, sex, race, and body size as surrogates for creatinine generation. Despite substantial advances in the accuracy of estimating equations based on creatinine during the past several years, no equation can overcome the limitations of creatinine as a filtration marker. None of these equations is expected to work as well in patients with extreme levels for creatinine generation, such as amputees, large or small individuals, patients with muscle-wasting conditions, or people with high or low levels of dietary meat intake (see Fig. 3.4). Because of differences among racial and ethnic groups according to muscle mass and diet, it is unlikely that equations developed in one racial or ethnic group will be accurate in multiethnic populations.

Cockcroft-Gault Formula

The Cockcroft-Gault formula (Fig. 3.5) estimates creatinine clearance from age, sex, and body weight in addition to serum creatinine.⁸ There is an adjustment factor for women that is based on a theoretical assumption of 15% lower creatinine generation due to lower muscle mass. Comparison to normal values for creatinine clearance requires computation of body surface area and adjustment to 1.73 m². Because of the inclusion of a term for weight in the numerator, this formula systematically overestimates creatinine clearance in patients who are edematous or obese.

There are three main limitations of the Cockcroft-Gault formula. First, it is not precise, in particular in the GFR range above 60 ml/min. Second, it estimates creatinine clearance rather than GFR; hence, it is expected to overestimate GFR. As discussed before, normal values for creatinine secretion are not well known. Third, it was derived by older assay methods for serum creatinine, which cannot be calibrated to newer assay methods, which would be expected to lead to a systematic bias in estimating creatinine clearance.

Importantly, before standardization of creatinine assays, the Cockcroft-Gault formula was widely used to assess

Equations for Estimating GFR

Cockcroft-Gault formula⁵

Male	$C_{cr} \text{ (ml/min)} = \frac{(140 - \text{age}) \times \text{weight}}{72 \times S_{cr}(\text{mg/dl})}$	or	$C_{cr} \text{ (ml/min)} = \frac{(140 - \text{age}) \times \text{weight}}{0.814 \times S_{cr}(\mu\text{mol/l})}$
Female	$C_{cr} \text{ (ml/min)} = \frac{(140 - \text{age}) \times \text{weight} \times 0.85}{72 \times S_{cr}(\text{mg/dl})}$	or	$C_{cr} \text{ (ml/min)} = \frac{(140 - \text{age}) \times \text{weight} \times 0.85}{0.814 \times S_{cr}(\mu\text{mol/l})}$

MDRD study equation (four-variable equation)⁷

$$\text{GFR (ml/min/1.73 m}^2\text{)} = 186 \times S_{cr} \text{ (mg/dl)}^{-1.154} \times \text{Age}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)}$$

or

$$\text{GFR (ml/min/1.73 m}^2\text{)} = 32,788 \times S_{cr} \text{ (}\mu\text{mol/l)}^{-1.154} \times \text{Age}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)}$$

MDRD Study Equation for Use with Standardized Serum Creatinine (Four-variable equation)⁷

$$\text{GFR (ml/min/1.73 m}^2\text{)} = 175 \times \text{Standardized } S_{cr}(\text{mg/dl)}^{-1.154} \times \text{age}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)}$$

or

$$\text{GFR (ml/min/1.73 m}^2\text{)} = 30,849 \times \text{Standardized } S_{cr}(\mu\text{mol/l)}^{-1.154} \times \text{age}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)}$$

CKD-EPI Equation for Use with Standardized Serum Creatinine¹²

$$\text{GFR (ml/min/1.73 m}^2\text{)} = 141 \times \min(S_{cr}/\kappa, 1)^\alpha \times \max(S_{cr}/\kappa, 1)^{1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ (if female)} \times 1.157 \text{ (if black)}$$

where κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, min indicates the minimum of S_{cr}/κ or 1, and max indicates the maximum of S_{cr}/κ or 1.

Female	$\leq 0.7 \rightarrow \text{GFR} = 144 \times (S_{cr}/0.7)^{-0.329}$	$\times (0.993)^{\text{Age}}$	$\times 1.157 \text{ (if black)}$
	$> 0.7 \rightarrow \text{GFR} = 144 \times (S_{cr}/0.7)^{-1.209}$		
Male	$\leq 0.9 \rightarrow \text{GFR} = 141 \times (S_{cr}/0.9)^{-0.411}$		
	$> 0.9 \rightarrow \text{GFR} = 141 \times (S_{cr}/0.9)^{-1.209}$		

*Age in years, weight in kg, S_{cr} , serum creatinine

pharmacokinetic properties of drugs in people with impaired kidney function, and it remains the standard for drug dosage adjustment in this setting. The accuracy of drug dosing recommendations based on the Cockcroft-Gault formula using creatinine values from modern assays remains an issue of debate. One study suggests that drug dosage adjustment guided by the Cockcroft-Gault formula is slightly less accurate than adjustments based on more accurate estimating equations.⁹

Modification of Diet in Renal Disease Study Equation

The Modification of Diet in Renal Disease (MDRD) study equation was originally expressed as a six-variable equation using serum creatinine, urea, and albumin concentrations in addition to age, sex, and race (African American versus Caucasian or other) to predict GFR as measured by urinary clearance of ¹²⁵I-iothalamate. The revised four-variable equation has now been re-expressed for use with standardized serum creatinine values (see Fig. 3.5).¹⁰ This equation has been validated in African Americans, people with diabetic kidney disease, and kidney transplant recipients, three groups not included in large numbers in the original MDRD study. Its validity is independent of the etiology of kidney disease.¹¹ The equation appears to underestimate GFR in populations with higher levels of GFR, such as patients with type 1 diabetes without microalbuminuria and people undergoing kidney transplant donor evaluation (Fig. 3.6). It has not been validated in children, pregnant women, or the

elderly (age >85 years). The MDRD study equation had greater precision and greater overall accuracy than the Cockcroft-Gault formula.

Many organizations now recommend GFR estimates as the primary method of clinical assessment of kidney function.¹² In 2004, the National Kidney Disease Education Program of the National Institute of Diabetes and Digestive and Kidney Diseases recommended that clinical laboratories in the United States report estimated GFR using the MDRD study equation when serum creatinine is reported.¹³ A recent survey by the College of American Pathologists revealed that more than 70% of clinical laboratories in the United States now follow this practice.⁶ Similarly, in 2006, the United Kingdom required hospital laboratories to report estimated GFR using the MDRD study equation with standardized creatinine measurement. Because of limitations in accuracy at higher levels, it has been recommended that GFR estimates be reported as a numerical value only if the GFR estimate is less than 60 ml/min per 1.73 m² and as “greater than 60 ml/min per 1.73 m²” for higher values.

Modifications of the MDRD study equation have now been reported in racial and ethnic populations other than African American and Caucasian.¹⁴ In general, these modifications improve the accuracy of the MDRD study equation in the study population, but there is some uncertainty because of inconsistencies between studies.¹⁴

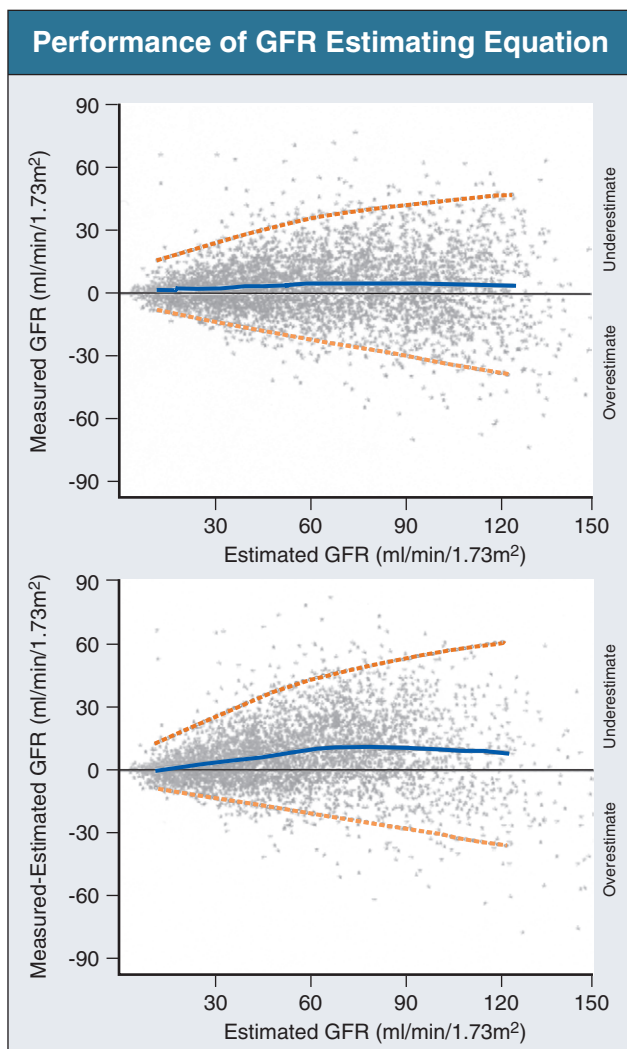

Figure 3.6 Comparison of performance of Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) and Modification of Diet in Renal Disease (MDRD) study equations. *Top*, Measured versus estimated GFR for the CKD-EPI equation. *Bottom*, Difference between measured and estimated versus estimated GFR for the MDRD study equation. Shown are smoothed regression line and 95% CI (computed by use of the lowest smoothing function in R), using quantile regression, excluding lowest and highest 2.5% of estimated GFR values. For the two equations, median bias (percentage of estimates within 30% of measured GFR [P_{30}]) is 2.5 (84) and 5.5 (81), respectively. To convert GFR from ml/min/1.73 m² to ml/s/m², multiply by 0.0167.

CKD-EPI Equation

A new estimating equation, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation (see Fig. 3.5), has been developed from a large database of subjects from research studies and patients from clinical populations with diverse characteristics, including people with and without kidney disease, diabetes, and a history of organ transplantation.¹⁵ The equation is based on the same four variables as the MDRD study equation but uses a two-slope “spline” to model the relationship between GFR and serum creatinine, which partially corrects the underestimation of GFR at higher levels seen with the MDRD study equation. It also incorporates slightly different relationships for age, sex, and race. As a result, the CKD-EPI equation is as accurate as the MDRD study equation at estimated GFR below 60 ml/min per 1.73 m² and more accurate at higher levels (see Fig. 3.6). The CKD-EPI equation is more accurate than the

MDRD study equation across a wide range of characteristics, including age, sex, race, body mass index, and presence or absence of diabetes or history of organ transplantation. With the CKD-EPI equation, it is now possible to report estimated GFR across the entire range of values without substantial bias. In our view, the CKD-EPI equation should replace the MDRD study equation for routine clinical use. However, GFR estimates are still limited by imprecision. As discussed later, it is likely that further improvements will require additional filtration markers.

UREA

The serum urea level has limited value as an index of GFR, in view of widely variable non-GFR determinants, primarily urea generation and tubular reabsorption (see Fig. 3.2).

Urea is a 60-d end product of protein catabolism by the liver. Factors associated with the increased generation of urea include protein loading from hyperalimentation and absorption of blood after a gastrointestinal hemorrhage. Catabolic states due to infection, corticosteroid administration, or chemotherapy also increase urea generation. Decreased urea generation is seen in severe malnutrition and liver disease.

Urea is freely filtered by the glomerulus and then passively reabsorbed in both the proximal and distal nephrons.¹ Owing to tubular reabsorption, urinary clearance of urea underestimates GFR. Reduced kidney perfusion in the setting of volume depletion and states of antidiuresis are associated with increased urea reabsorption. This leads to a greater decrease in urea clearance than the concomitant decrease in GFR. At GFR of less than approximately 20 ml/min per 1.73 m², the overestimation of GFR by creatinine clearance due to creatinine secretion is approximately equal to the underestimation of GFR by urea clearance due to urea reabsorption.

CYSTATIN C

Cystatin C Metabolism and Excretion

Cystatin C (see Fig. 3.2) is a 122-amino acid protein with a molecular mass of 13 kd. It has multiple biologic functions including extracellular inhibition of cysteine proteases, modulation of the immune system, exertion of antibacterial and antiviral activities, and modification of the body's response to brain injury.¹⁶ The serum concentration of cystatin C remains constant from approximately 1 to 50 years of age. In analyses of the National Health and Nutrition Examination Survey (NHANES) III, the median and upper 99th percentile levels of serum cystatin C for people 20 to 39 years of age without history of hypertension and diabetes were 0.85 mg/l and 1.12 mg/l, respectively, with levels lower in women, higher in non-Hispanic whites, and increasing steeply with age.¹⁷

Cystatin C has been thought to be produced at a constant rate by a “housekeeping” gene expressed in all nucleated cells.¹⁶ Cystatin C is freely filtered at the glomerulus because of its small size and basic pH.^{16,18} After filtration, approximately 99% of the filtered cystatin C is reabsorbed by the proximal tubular cells, where it is almost completely catabolized, with the remaining uncatabolized form eliminated in the urine.¹⁸ There is some evidence for the existence of tubular secretion as well as extra-renal elimination, which has been estimated to be between 15% and 21% of renal clearance.¹⁶

Because cystatin C is not excreted in the urine, it is difficult to study its generation and renal handling. Thus, understanding

of determinants of cystatin C other than GFR relies on epidemiologic associations. There are suggestions that inflammation, adiposity, thyroid diseases, certain malignant neoplasms, and use of glucocorticoids may increase cystatin C levels. In two studies, key factors that led to higher levels of cystatin C after adjustment for creatinine clearance or measured GFR were older age, male gender, fat mass, white race, diabetes, higher C-reactive protein level and white blood cell count, and lower serum albumin level.^{19,20} Altogether, these studies suggest that factors other than GFR must be considered in interpreting cystatin C levels.

Assay

There are currently two main automated methods for assay of cystatin C: immunoassays based on turbidimetry (particle-enhanced turbidimetric immunoassay, PETIA) and nephelometry (particle-enhanced nephelometric immunoassay, PENIA). The two methods result in different results.¹⁶ International standardization of the assay is in process. The assays are considerably more expensive than those for creatinine determination.

Use as a Filtration Marker

Some studies show that elevations in cystatin C level are a better predictor of the risk of cardiovascular disease and total mortality than is an estimated GFR based on serum creatinine concentration. Whether this is due to its superiority as a filtration marker or to confounding by non-GFR determinants of cystatin C and creatinine remains to be determined.¹ Several studies have compared accuracy of serum cystatin C and creatinine in relation to measured GFR. The majority of studies have found serum cystatin C levels to be a better estimate of GFR than serum creatinine concentration is. However, cystatin C or equations based on cystatin C are not more accurate than creatinine-based estimating equations.¹⁶ In studies of patients with chronic kidney disease, the combination of the two markers resulted in the most accurate estimate.²¹ In certain populations, such as in children, elderly, transplant recipients, patients with neuromuscular diseases or liver disease, or those with higher levels of GFR, in whom serum creatinine-based equations are less accurate, cystatin C may result in a more accurate estimate, but this has not been rigorously evaluated.¹⁶ In patients with acute kidney injury, serum cystatin C increases more rapidly than serum creatinine.²² More data are required to establish whether it is a more sensitive indicator of rapidly changing kidney function than creatinine is.

In the future, GFR estimating equations using the combination of serum cystatin C and creatinine may have potential to provide more accurate estimates of GFR than do equations using serum creatinine. However, this is feasible only after standardization, widespread availability, and cost reductions of cystatin C assays as well as further investigation of non-GFR determinants of serum cystatin C.

CLINICAL APPLICATION OF ESTIMATED GLOMERULAR FILTRATION RATE

Chronic Kidney Disease

Estimation of GFR is necessary for the detection, evaluation, and management of chronic kidney disease (CKD). Current guidelines recommend testing of patients at increased risk of CKD for albuminuria as a marker of kidney damage or a reduced estimated GFR to assess kidney function and staging of the severity

of CKD by the level of the estimated GFR. Use of serum creatinine alone as an index of GFR is unsatisfactory and can lead to delays in detection of CKD and misclassification of the severity of CKD. Use of estimating equations allows direct reporting of GFR estimates by clinical laboratories whenever serum creatinine is measured. Current estimating equations will be less accurate in people with factors affecting serum creatinine concentration other than GFR (see Fig. 3.4). In these situations, more accurate GFR estimates require a clearance measurement, by use of either an exogenous filtration marker or a timed urine collection for creatinine clearance.² In the future, improved estimating equations using creatinine and possibly cystatin C will allow more accurate GFR estimates.

Acute Kidney Injury

In the non-steady state, there is a lag before the rise in serum level due to the time required for retention of an endogenous filtration marker (Fig. 3.7). Conversely, after recovery of GFR, there is a lag before the excretion of the retained marker. During this time, neither the serum level nor the GFR estimated from the serum level accurately reflects the measured GFR. Nonetheless, a change in the estimated GFR in the non-steady state can be a useful indication of the magnitude and direction of the change in measured GFR. If the estimated GFR is falling, the decline in estimated GFR is less than the decline in measured GFR. Conversely, if the estimated GFR is rising, the rise in estimated GFR is greater than the rise in measured GFR. The more rapid the change in estimated GFR, the larger the change

Figure 3.7 Effect of a sudden decrease in glomerular filtration rate on endogenous marker excretion, production, balance, and plasma marker concentration. (Modified with permission from reference 4.)

in measured GFR. When the estimated GFR reaches a new steady state, it more accurately reflects measured GFR.

MARKERS OF TUBULAR DAMAGE

Low-molecular-weight plasma proteins are readily filtered by the glomerulus and subsequently reabsorbed by the proximal tubule in normal subjects, with the result that only small amounts of the filtered proteins appear in the urine. The urinary excretion of these proteins rises when proximal tubular reabsorption is impaired. Because there is no distal tubular reabsorption, measurement of urinary low-molecular-weight proteins has been widely accepted as a marker of proximal tubular damage. Examples of low-molecular-weight proteins that could be measured in clinical practice are β_2 -microglobulin (11,800 d), the light chain of the class I major histocompatibility antigens; α_1 -macroglobulin (33,000 d), a glycosylated protein synthesized in the liver; and retinol-binding protein. β_2 -Microglobulin is unstable in acidic urine (pH <6), leading to underestimation, whereas α_1 -macroglobulin is stable and not readily affected by urine pH. Urine cystatin C and *N*-acetyl- β -glucosaminidase (NAG) have also been proposed as markers of tubular damage. Two more recently described markers of tubular damage are urinary kidney injury molecule 1 (KIM-1) and neutrophil gelatinase-associated lipocalin (NGAL).²³ These and other urinary markers of tubular damage under investigation are discussed further in Chapter 68.

Urinalysis

Giovanni B. Fogazzi

DEFINITION

Urinalysis is one of the basic tests to evaluate kidney and urinary tract disease. When a patient is first seen by a nephrologist, urinalysis should always be performed. Dipsticks are the most widely used method for urinalysis, but the nephrologist should be aware of their limitations, especially in detecting urine proteins other than albumin. Urine microscopy should ideally be performed by trained nephrologists rather than by clinical laboratory personnel, who are often unable to identify important features^{1,2} and are usually unaware of the clinical correlates of the findings.

URINE COLLECTION

The way urine is collected and handled can greatly influence the results (Fig. 4.1). Written instructions should be given to the patient as to how to perform a urine collection.³ First, strenuous physical exercise (e.g., running, soccer match) must be avoided in the 72 hours preceding the collection to avoid exercise-induced proteinuria and hematuria or cylindruria. In women, urinalysis should also be avoided during menstruation because blood contamination can easily occur. The first or second morning urine specimen is recommended.³

After the washing of hands, women should spread the labia of the vagina and men withdraw the foreskin of the glans. The external genitalia are washed and wiped dry with a paper towel, and the “midstream” urine is collected after the first portion is discarded.³ The same procedures can also be used for children; for small infants, bags for urine are often used, even though these carry a high probability of contamination. A suprapubic bladder puncture may occasionally be necessary. Urine can also be collected through a bladder catheter, although the catheter may cause hematuria. Permanent indwelling catheters are commonly associated with bacteriuria, leukocyturia, hematuria, and candiduria.

The container for urine should be provided by the laboratory or bought in a pharmacy. It should be clean, have a capacity of at least 50 to 100 ml, and have a diameter opening of at least 5 cm to allow easy collection. It should have a wide base to avoid accidental spillage and should be capped.³ The label should identify the patient as well as the hour of urine collection.

Several elements (but especially leukocytes) can lyse rapidly after collection, and the best preservation method to minimize this is uncertain. Refrigeration of specimens at +2°C to +8°C assists preservation but may allow precipitation of phosphates or uric acids, which can hamper examination of the sample.

Formaldehyde, glutaraldehyde, CellFIX (a formaldehyde-based fixative),⁴ and tubes containing a lyophilized borate-formate-sorbitol powder⁵ are good preservatives for the formed elements of urine.

PHYSICAL CHARACTERISTICS

Color

The color of normal urine ranges from pale to dark yellow and amber, depending on the concentration of the urochrome. Abnormal changes in color can be due to pathologic conditions, drugs, or foods.

The main pathologic conditions that can cause color changes of the urine are gross hematuria, hemoglobinuria, or myoglobinuria (pink, red, brown, or black urine); jaundice (dark yellow to brown urine); chyluria (white milky urine)⁶; massive uric acid crystalluria (pink urine); urinary infection due to some types of *Escherichia coli* (velvet urine); and porphyrinuria and alkaptonuria (red urine turning black on standing).

The main drugs responsible for abnormal urine color are rifampin (yellow-orange to red urine); phenytoin (red urine); chloroquine and nitrofurantoin (brown urine); triamterene, propofol, and blue dyes of enteral feeds (green urine); methylene blue (blue urine); and metronidazole, methyl dopa, and imipenem-cilastatin (darkening on standing).

Among foods are beetroot (red urine), senna and rhubarb (yellow to brown or red urine), and carotene (brown urine).

Turbidity

Normal urine is transparent. Urine can be turbid because of an increased concentration of any urine particle. The most frequent causes of turbidity are urinary tract infection, heavy hematuria, and contamination from genital secretions. The absence of turbidity is not a reliable criterion by which to judge a urine sample because pathologic urine can be transparent.

Odor

A change in urine odor may be caused by the ingestion of some foods, such as asparagus. A pungent odor, due to the production of ammonia, is typical of most bacterial urinary tract infection, whereas there is often a sweet or fruity odor with ketones in the urine. Some rare conditions confer a characteristic odor to the urine. These include maple-syrup urine disease (maple syrup odor), phenylketonuria (musty or mousy odor), isovaleric

Procedures for Preparation and Examination of the Urine Sediment

Written instructions to the patients for urine collection
Collection in disposable containers of the second urine of the morning after discarding the first few milliliters of urine
Sample handling and analysis within 3 h from collection
Centrifugation of a 10 ml aliquot of urine at 400 g for 10 min
Removal by suction of 9.5 ml of supernatant urine
Gentle but thorough resuspension with a pipette of the sediment in the remaining 0.5 ml of urine
Transfer by a pipette of 50 μ l of resuspended urine to a slide
Covering of sample with a 24 \times 32-mm coverslip
Examination of the urine sediment by a phase contrast microscope at \times 160 and \times 400
Use of polarized light to identify doubtful lipids and crystals
Match the microscopic findings with dipstick for pH, specific gravity, hemoglobin, leukocyte esterase, nitrites, and albumin (the presence of albumin orients the examination of the sample toward a glomerular disease)
Cells expressed as lowest–highest number seen per high-power field, casts as number per low-power field, all the other elements (e.g., bacteria, crystals) on a scale from 0 to ++++

Figure 4.1 Procedures for preparation and examination of the urine sediment used in the author's laboratory.

acidemia (sweaty feet odor), and hypermethioninemia (rancid butter or fishy odor).

Relative Density

Relative density can be measured by a number of methods.

Specific gravity (SG) is a function of the number and weight of the dissolved particles and is influenced by urine temperature, proteins, glucose, and radiocontrast media. Historically, SG was measured by a urinometer, which is a weighted float marked with a scale from 1.000 to 1.060. Today, SG is most commonly measured by dry chemistry, which is incorporated into dipsticks. In the presence of cations, protons are released by a complexing agent and produce a color change in the indicator bromthymol blue from blue to blue-green to yellow. Underestimation occurs with urine pH above 6.5, whereas overestimation is found with urine protein concentration above 7.0 g/l. In addition, nonionized molecules, such as glucose and urea, are not detected. Not surprisingly, this method does not strictly correlate with the results obtained by osmolality⁷ and refractometry.⁸

SG of 1.000 to 1.003 is consistent with marked urinary dilution, such as observed with diabetes insipidus or water intoxication. SG of 1.010 is often called isosthenuric urine because it is of similar SG (and osmolality) as plasma, so it is often observed in conditions in which urinary concentration is impaired, such as acute tubular necrosis (ATN) and chronic kidney disease. SG above 1.040 almost always indicates the presence of some extrinsic osmotic agent (such as contrast material).

Osmolality depends on the number of particles present and is measured by an osmometer. It is not influenced by urine temperature and protein concentrations. However, high glucose concentrations significantly increase osmolality (10 g/l of glucose = 55.5 mOsm/l).

Refractometry is based on measurement of the refractive index, which depends on the weight and the size of solutes per unit volume, and correlates well with osmolality.⁷ Refractometers are simple to use and have the major advantage of requiring only one drop of urine. For these reasons, the use of refractometry rather than of SG is suggested, even though the factors that can interfere with SG can also interfere with refractometry.

CHEMICAL CHARACTERISTICS

Figure 4.2 summarizes the main false-negative and false-positive results that can occur with urine dipstick testing.

pH

The pH is determined by dipsticks that cover the pH range 5.0 to 8.5 or to 9.0. With use of dipsticks, significant deviations from true pH are observed for values below 5.5 and above 7.5. Therefore, a pH meter with a glass electrode is mandatory if an accurate measurement is necessary.³

Urine pH reflects the presence of hydrogen ions, but this does not necessarily reflect the overall acid load in the urine as most of the acid is excreted as ammonia. A low pH is often observed with metabolic acidosis (in which acid is secreted), with high-protein meals (which generate more acid and ammonia), and with volume depletion (in which aldosterone is stimulated, resulting in an acid urine). Indeed, low urine pH may help distinguish prerenal acute renal impairment from ATN (which is typically associated with a higher pH). High pH is often observed with renal tubular acidosis (especially distal, type 1; see Chapter 12), with vegetarian diets (due to minimal nitrogen and acid generation), and with infection with urease-positive organisms (such as *Proteus*) that generate ammonia from urea.

Measurement of urine pH is also needed for the interpretation of urinalysis (see later, *Leukocyte Esterase* and *Urine Microscopy*).

Hemoglobin

Hemoglobin is detected by a dipstick on the basis of the pseudoperoxidase activity of the heme moiety of hemoglobin, which catalyzes the reaction of a peroxide and a chromogen to produce a colored product. The presence of hemoglobin is shown as green spots, which are due to intact erythrocytes, or as a homogeneous diffuse green pattern, which is common with marked hematuria because of the high number of erythrocytes that cover the whole pad surface. It may also be observed if lysis of erythrocytes has occurred on standing or as a consequence of alkaline urine pH or a low specific gravity (especially <1.010).

The most important reasons for a positive test result in the absence of red cells are hemoglobinuria deriving from intravascular hemolysis, myoglobinuria deriving from rhabdomyolysis, and a high concentration of bacteria with pseudoperoxidase activity (Enterobacteriaceae, staphylococci, and streptococci).⁹

False-negative results are mainly due to ascorbic acid, a strong reducing agent, which can cause low-grade microscopic hematuria to be completely missed.¹⁰

Urine Dipstick Testing		
Parameter	False-negative Results	False-positive Results
Specific gravity	Urine pH >6.5	Increased values in the presence of protein >7.0 g/l Ketoacids
pH	Reduced values in the presence of formaldehyde	—
Hemoglobin	Ascorbic acid Delayed examination High density of urine Formaldehyde (0.5 g/l)	Myoglobin Microbial peroxidases Oxidizing agents Hydrochloric acid
Glucose	Ascorbic acid Bacteria	Oxidizing detergents Hydrochloric acid
Albumin	Immunoglobulin light chains Tubular proteins Globulins Abnormally colored urine	Urine pH \geq 9.0 Quaternary ammonium detergents Chlorhexidine Polyvinylpyrrolidone
Leukocyte esterase	High density of urine Vitamin C (intake: g/day) Protein >5.0 g/l, Glucose >20.0 g/l Cephalothin (+++), Tetracycline (+++), Cephalexin (++), Tobramycin (+)	Oxidizing detergents Formaldehyde (0.4 g/l) Sodium azide Abnormally colored urine due to beet
Nitrites	Bacteria that do not reduce nitrates to nitrites Short bladder incubation time No vegetables in diet	Abnormally colored urine
Ketones	Improper storage	Free sulfhydryl groups (e.g., captopril) Levodopa Abnormally colored urine

Figure 4.2 Urine dipstick testing. Main false-negative and false-positive results of urine dipsticks.

Detection of hemoglobin by dipstick has a high specificity and a low sensitivity.^{11,12}

Glucose

Glucose is also commonly detected by dipstick. Glucose, with glucose oxidase as catalyst, is first oxidized to gluconic acid and hydrogen peroxide. Then, through the catalyzing activity of a peroxidase, hydrogen peroxide reacts with a reduced colorless chromogen to form a colored product. This test detects concentrations of 0.5 to 20 g/l. When more precise quantification of urine glucose is needed, enzymatic methods such as hexokinase must be used.

False-negative results occur in the presence of ascorbic acid and bacteria. False-positive findings may be observed in the presence of oxidizing detergents and hydrochloric acid.

Protein

Physiologic proteinuria does not exceed 150 mg/24 h for adults and 140 mg/m² for children. Three different approaches can be used for the evaluation of proteinuria.

Dipstick This relies on the fact that the presence of protein in a buffer causes a change of pH that is proportional to the concentration of protein itself. The dipstick changes its color (from pale green to green and blue) according to the pH changes induced by the protein. This method is highly sensitive for albumin (detection limit of approximately 0.20 to 0.25 g/l), whereas it has a very low sensitivity to other proteins such as tubular proteins and light-chain immunoglobulins.

Dipstick allows only a semiquantitative measurement of urine albumin, which is expressed on a scale from 0 to +++ or +++++. Although, in general, + albumin corresponds to 800 mg/l, ++ with 1450 mg/l, and +++ with 3000 mg/l, there is wide variance. Therefore, accurate quantification requires other methods, such as turbidimetric or dye-binding techniques (e.g., benzethonium chloride or pyrogallol red–molybdate colorimetric method).

The 24-Hour Protein Excretion This remains the reference (gold standard) method. It averages the variation of proteinuria due to the circadian rhythm and is the most accurate for monitoring of proteinuria during treatment, but it can be impractical in some settings (e.g., outpatients, elderly patients). Moreover, this method is subject to error due to overcollection or

undercollection. One advantage is that 24-hour urine protein is usually measured by methods that quantify total protein rather than simply albumin, and hence this can result in detection of light chains in subjects with myeloma.

Protein-Creatinine Ratio on a Random Urine Sample This is a practical alternative to the 24-hour urine collection.¹³ It is easy to obtain, it is not influenced by variation in water intake and rate of diuresis, and the same sample can also be used for microscopic investigation.

There is a strong correlation between the protein-creatinine ratio in a random urine sample and the 24-hour protein excretion.¹⁴ However, although a normal protein-creatinine ratio is sufficient to rule out pathologic proteinuria, an elevated protein-creatinine ratio should be confirmed and quantified with a 24-hour collection. Moreover, the reliability of the protein-creatinine ratio for monitoring of proteinuria during treatment is still not proven. A discussion of how to measure and to monitor proteinuria in such patients is provided in Chapter 76.

Specific Protein Assays

A qualitative analysis of urine proteins can be performed by electrophoresis on cellulose acetate or agarose after protein concentration or by use of very sensitive stains, such as silver and gold. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) can be used to identify the different urine proteins by molecular weight and to characterize the pattern of proteinuria.¹⁵

In some circumstances, measurement of a single specific protein may be informative, for example, neutrophil gelatinase-associated lipocalin for early detection of acute kidney injury (AKI).¹⁶

Bence Jones proteinuria can be suspected when the dipstick measurement for proteinuria is negative (because it mainly detects albumin) yet the 24-hour urine protein is elevated. Confirmation of free immunoglobulin light chains in the urine requires immunofixation.¹⁷

Selectivity of proteinuria in nephrotic syndrome can be assessed by the ratio of the clearance of IgG (molecular weight 160,000) to the clearance of transferrin (molecular weight 88,000).¹⁸ Although it is not widely used, highly selective proteinuria (ratio <0.1) in nephrotic children suggests the diagnosis of minimal change disease and predicts corticosteroid responsiveness. Selectivity of proteinuria combined with SDS-PAGE and the excretion of low-molecular-weight proteins, such as α_1 -microglobulin, is reported to predict the outcome and response to therapy in minimal change disease, focal segmental glomerulosclerosis, and membranous nephropathy.¹⁹

Leukocyte Esterase

This dipstick evaluates the presence of leukocytes on the basis of an indoxyl esterase activity released from lysed neutrophil granulocytes and macrophages. Leukocyte esterase may be positive when microscopy is negative when leukocytes are lysed because of low density, alkaline pH, or delay in sample handling and examination. The detection limit of the dipstick is 20×10^6 white blood cells per liter.

False-positive results are rare but may occur when formaldehyde is used as a urine preservative. False-negative results are more common from high glucose or protein concentrations (20 g/l and 5 g/l, respectively) or in the presence of cephalothin

and tetracycline (strong inhibition), cephalexin (moderate inhibition), or tobramycin (mild inhibition). The sensitivity is also reduced by high specific gravity because this prevents leukocyte lysis. Sensitivity varies from 76% to 94% and specificity from 68% to 81%.^{20,21}

Nitrites

The dipstick nitrites test detects bacteria that reduce nitrates to nitrites by nitrate reductase activity. This includes most gram-negative uropathogenic bacteria but not *Pseudomonas*, *Staphylococcus albus*, and *Enterococcus*. A positive test result also requires a diet rich in nitrates (vegetables), which form the substrate for nitrite production, and sufficient bladder incubation time. Thus, it is not surprising that the sensitivity of this test is low, whereas specificity is more than 90%.²²

Bile Pigments

Measurements of urinary urobilinogen and bilirubin concentrations have lost their clinical value in the detection of liver disease after the introduction of serum tests of liver enzyme function.

Ketones

This dipstick tests for the presence of acetoacetate and acetone (but not β -hydroxybutyrate), which are excreted into urine during diabetic acidosis or during fasting, vomiting, or strenuous exercise. It is based on the reaction of the ketones with nitroprusside.

URINE MICROSCOPY

The urine sediment can contain cells, lipids, casts, crystals, organisms, and contaminants.

Methods

The first or second urine specimen of the morning should be collected, following the procedures described earlier (see [Urine Collection](#) and [Fig 4.1](#)). To avoid the lysis of elements, an aliquot of urine should be rapidly centrifuged and concentrated, after which a standardized volume of resuspended urine should be transferred to the slide and covered with a coverslip. The use of noncentrifuged samples greatly reduces sensitivity, especially for rare findings such as erythrocyte casts.

Phase contrast microscopy is recommended³ because it improves the identification of particles, and polarized light is mandatory for the correct identification of lipids and crystals.³ At least 10 microscopic fields, in different areas of the sample, should be examined at both low and high magnification.³ More extensive examination may be required in certain clinical settings. For instance, for patients with isolated microscopic hematuria of unknown origin, always examine 50 low-power fields ($\times 160$) to search for erythrocyte casts.

For correct examination, both pH and specific gravity of the sample should be known. Both alkaline pH and low specific gravity (especially <1.010) favor the lysis of erythrocytes and leukocytes, which can cause discrepancies between dipstick readings and the microscopic examination (see earlier). Alkaline pH also impairs the formation of casts and favors the precipitation of phosphates.

The various elements observed are quantified as number per microscopic field, and if counting chambers are used, the elements are quantified as number per milliliter. Counting chambers allow a precise quantitation but are rarely used in everyday practice.

Cells

Erythrocytes

Erythrocytes have a diameter of 4 to 10 μm . There are two main types of urinary erythrocytes: isomorphic, with regular shapes and contours, derived from the urinary excretory system; and dysmorphic, with irregular shapes and contours, which are of glomerular origin (Fig. 4.3A, B).²³ Hematuria has been defined as nonglomerular when isomorphic erythrocytes predominate (>80% of total erythrocytes) and as glomerular when dysmorphic erythrocytes prevail (>80% of total erythrocytes).²⁴ Some diagnose glomerular hematuria when the two types of cells are in the same proportion (so-called mixed hematuria)²⁵ or when at least 5% of erythrocytes examined are acanthocytes,²⁶ a subtype of dysmorphic erythrocytes with a characteristic appearance that is due to the presence of one or more blebs protruding from a ring-shaped body (Fig. 4.3B, *inset*).

Glomerular hematuria is identified when there are 40% or more dysmorphic erythrocytes or 5% or more acanthocytes or one or more red cell casts in 50 low-power fields ($\times 160$ magnification). With this method in isolated microscopic hematuria, a good correlation between urinary and renal biopsy findings was found.²⁷

The distinction between glomerular and nonglomerular hematuria aids in the evaluation of patients with isolated microscopic hematuria.²⁸ However, the evaluation of erythrocyte morphology is subjective and requires experience, which has limited its widespread introduction into clinical practice.

Erythrocyte dysmorphism is thought to result from deformation of the erythrocyte while it is passing through gaps of the glomerular basement membrane followed by physicochemical insults occurring while the erythrocyte passes through the tubular system.²⁹ In glomerulonephritis (GN), the number of urinary erythrocytes may also be of clinical significance; in proliferative GN, the number of erythrocytes is significantly higher than in patients with nonproliferative GN.³⁰

Leukocytes

Neutrophils range from 7 to 15 μm in diameter and are the most frequently found leukocytes in the urine. They are identified by their granular cytoplasm and lobulated nucleus (Fig. 4.3C). Neutrophils often indicate lower or upper urinary tract infections but may result from genital secretions, especially in young women. They can also be found in proliferative or crescentic GN³⁰ and in acute or chronic interstitial nephritis.

Eosinophils, once considered a marker of acute allergic interstitial nephritis, are today seen as nonspecific particles because they may be present in various types of GN, prostatitis, chronic pyelonephritis, urinary schistosomiasis, and cholesterol embolism.^{31,32} Eosinophiluria in the evaluation of acute interstitial nephritis is discussed further in Chapter 60.

Lymphocytes may indicate acute cellular rejection in renal allograft recipients, but their identification requires staining, and this technique is not widely used in clinical practice. Lymphocytes are also a typical finding in patients with chyluria.⁶

Macrophages have only recently been identified in urinary sediments. They are mononucleated or multinucleated cells of variable size (diameter, 13 to 95 μm) and variable appearance: granular (Fig. 4.3D), vacuolar, phagocytic (when cytoplasm contains bacterial debris, cell fragments, destroyed erythrocytes, crystals), or homogeneous (when cytoplasm does not contain granules or other particles). In patients with the nephrotic syndrome, macrophages may be engorged with lipid droplets, appearing as “oval fat bodies.”³³ Macrophages have been found in the urine of patients with active GN,³³ including IgA nephropathy.³⁴ In our experience, macrophages are also present in the urine of transplant recipients with BK virus infection (see later discussion). However, urinary macrophages are not yet considered diagnostic of any specific condition.

Renal Tubular Epithelial Cells

These cells derive from the exfoliation of the tubular epithelium. In the urine, they can differ in size (diameter, ~9 to 25 μm) and shape (from roundish to rectangular or columnar; Fig. 4.3E). They are a marker of tubular damage and are not found in health but are found in AKI, acute interstitial nephritis, and acute cellular rejection of a renal allograft. In smaller numbers, they are also found in glomerular diseases.³⁰ In AKI, renal tubular epithelial cells are frequently damaged and necrotic; in other conditions, such as glomerular diseases, they usually have a normal appearance.

Renal tubular epithelial cells may be present in casts (epithelial casts), although the two are not always seen together.³⁰

Uroepithelial Cells

These cells derive from the exfoliation of the uroepithelium, which lines the urinary tract from calyces to the bladder in women and to the proximal urethra in men. It is a multilayered epithelium, with small cells in the deep layers and larger cells in the superficial layers.

Cells of the deep layers (diameter, ~10 to 38 μm ; Fig. 4.3F), when they are present in large numbers, reflect severe damage due to neoplasia, stones, or even ureteral stents.³⁵ Cells of the superficial layers (diameter, ~17 to 43 μm ; Fig. 4.3G) are a common finding, especially in urinary tract infections.

Squamous Cells

These cells (diameter, 17 to 118 μm ; Fig. 4.3H) derive from the urethra or from the external genitalia. In large numbers, they indicate urine contamination from genital secretions.

Lipids

Lipids may appear as spherical, translucent, or yellow drops of different size. They can be free in the urine (isolated or in clusters; Fig. 4.4A) or fill the cytoplasm of tubular epithelial cells or macrophages.³³ When they are entrapped within casts, lipids form fatty casts. Lipids can also appear as cholesterol crystals (see later, *Crystals*). Under polarized light, lipids have the appearance of Maltese crosses (Fig. 4.4B).

Lipids in the urine are typical of glomerular diseases associated with marked proteinuria, usually but not invariably in the nephrotic range. They can also be found in sphingolipidoses such as Fabry's disease. By electron microscopy, lipid particles in Fabry's disease differ from those in nephrotic syndrome by the appearance of intracellular and extracellular electron-dense lamellae and alternating dark and clear layers arranged in concentric whorls.³⁶

Figure 4.3 Urinary sediment cells. **A**, Isomorphic nonglomerular erythrocytes. The arrows indicate the so-called crenated erythrocytes, which are a frequent finding in nonglomerular hematuria. **B**, Dysmorphic glomerular erythrocytes. The dysmorphism consists mainly of irregularities of the cell membrane. *Inset*, Acanthocytes with their typical ring-formed cell bodies with one or more blebs of different sizes and shapes. **C**, Neutrophils. Note their typical lobulated nucleus and granular cytoplasm. **D**, A granular phagocytic macrophage (diameter about 60 μm).

Casts

Casts are cylindrical and form in the lumen of distal renal tubules and collecting ducts. Their matrix is due to Tamm-Horsfall glycoprotein (also called uromodulin), which is secreted by the cells of the thick ascending Henle's loop. Trapping of particles within the cast matrix results in casts with different appearances

and clinical significance (Fig. 4.5). The trapping of cells within the matrix causes the appearance of erythrocytic, leukocytic, or renal tubular cell casts. Degradation can transform leukocyte or epithelial casts into coarse granular casts. Fine granular casts are mostly due to the trapping within the matrix of the casts of lysosomes containing serum ultrafiltered proteins.

Figure 4.3, cont'd **E**, Different types of renal tubular cells. **F**, Two cells from the deep layers of the uroepithelium. **G**, Three cells from the superficial layers of the uroepithelium. Note the difference in shape and ratio of nucleus to cytoplasm existing between the two types of uroepithelial cells. **H**, Squamous cells. (All images by phase contrast microscopy; original magnification $\times 400$.)

- *Hyaline casts* are colorless with a low refractive index (Fig. 4.6A). They are easily seen with phase contrast microscopy but can be overlooked when bright-field microscopy is used. Hyaline casts may occur in normal urine, especially in volume depletion, in which urine is concentrated and acidic (both favoring precipitation of Tamm-Horsfall protein). In patients with renal disease, they are usually associated with other types of casts.³⁰
- *Hyaline-granular casts* contain granules within the hyaline matrix (Fig 4.6B). Rare but possible in normal individuals, they are common in GN.³⁰
- *Granular casts* can be either finely granular (Fig. 4.6C) or coarsely granular. Both types are typical of renal disease but not more specific.
- *Waxy casts* derive their name from their appearance, which is similar to that of melted wax (Fig. 4.6D). The nature of

waxy casts is still unknown. They are typical of patients with renal failure, and in our experience, they are also frequent in patients with rapidly progressive GN.

- *Fatty casts* contain variable amounts of lipid droplets, isolated, in clumps, or packed. They are typical of glomerular diseases associated with marked proteinuria or the nephrotic syndrome.
- *Erythrocyte (red cell) casts* may contain a few erythrocytes (Fig. 4.6E) or so many that the matrix of the cast cannot be identified. The finding of erythrocyte casts indicates hematuria of glomerular origin. Examination for erythrocyte casts is of particular importance in patients with isolated microscopic hematuria of unknown origin.²⁷
- *Hemoglobin casts* have a brownish hue and often a granular appearance deriving from the degradation of erythrocytes entrapped within the casts (Fig.

Figure 4.4 Two large aggregates of lipid droplets. Scattered in the specimen, there also are isolated fatty droplets (*arrows*). **A**, As seen by phase contrast microscopy. **B**, Under polarized light, which shows the typical Maltese crosses with their symmetric arms. (Original magnification $\times 400$.) For full morphologic details about these particles, see [reference 36](#).

Figure 4.5 Main types of casts and their clinical significance.

Clinical Significance of Urinary Casts	
Cast	Main Clinical Associations
Hyaline	Normal subject and renal disease
Hyaline-granular	Normal subject and renal disease
Granular	Renal disease
Waxy	Renal impairment; rapidly progressive renal disease
Fatty	Marked proteinuria; nephrotic syndrome
Erythrocyte	Glomerular hematuria; proliferative or necrotizing glomerulonephritis
Hemoglobin	The same as the erythrocyte cast; hemoglobinuria due to intravascular hemolysis
Leukocyte	Acute interstitial nephritis; acute pyelonephritis; proliferative glomerulonephritis
Renal tubular epithelial cell (epithelial casts)	Acute tubular necrosis; acute interstitial nephritis; proliferative glomerulonephritis; nephrotic syndrome
Myoglobin	Rhabdomyolysis
Bacterial, fungal	Bacterial or fungal infection in the kidney

Figure 4.6 Casts. **A**, Hyaline cast. **B**, Hyaline-granular cast. **C**, Finely granular cast.

Continued

4.6F). Therefore, hemoglobin casts have the same clinical meaning as erythrocyte casts. However, they may also derive from free hemoglobinuria in patients with intravascular hemolysis.

- *Leukocyte casts* contain variable amounts of polymorphonuclear leukocytes (Fig. 4.6G). They are found in acute pyelonephritis and acute interstitial nephritis. In GN, they are the rarest type of cast.³⁰
- *Epithelial casts* contain variable numbers of renal tubular cells, which can be identified by their prominent nucleus (Fig. 4.6H). Epithelial casts are a typical finding in ATN and acute interstitial nephritis. However, they are also frequent (even though in small numbers) in GN³⁰ and in the nephrotic syndrome.³⁵
- *Myoglobin casts* contain myoglobin and may be similar to hemoglobin casts (Fig. 4.6F), from which they can be distinguished through knowledge of the clinical setting. They are observed in the urine of patients with AKI associated with rhabdomyolysis.
- *Casts containing microorganisms* (bacteria and yeasts) indicate renal infection.
- *Casts containing crystals* indicate that crystals derive from the renal tubules. They are an important diagnostic element

in crystalluric forms of AKI, such as acute urate nephropathy.

Crystals

Correct identification of urine crystals requires knowledge of crystal morphologies, urine pH, and appearances under polarizing light.³⁷ Examination of the urine for crystals is informative in the assessment of patients with stone disease, with some rare inherited metabolic disorders, and with suspected drug nephrotoxicity. The following are the main crystals of the urine.

Uric Acid Crystals and Amorphous Uric Acids

Uric acid crystals have an amber color and a wide spectrum of appearances, including rhomboids and barrels (Fig. 4.7A). These crystals are found only in acid urine (pH ≤ 5.8) and are polychromatic under polarizing light.

Amorphous uric acids are tiny granules of irregular shape that also precipitate in acid urine. They are identical to amorphous phosphates, which, however, precipitate in alkaline pH. In addition, whereas uric acid crystals polarize light, phosphates do not.³⁵

Figure 4.6, cont'd D, Waxy cast. E, Erythrocyte casts. F, Hemoglobin casts (note typical brownish hue).

Figure 4.6, cont'd **G**, Leukocyte cast. The polymorphonuclear leukocytes are identifiable by their lobulated nucleus (*arrows*). **H**, Epithelial cell casts. Renal tubular cells are identifiable by their large nucleus. (All images by phase contrast microscopy; original magnification $\times 400$.) For full morphologic details about these particles, see [reference 36](#).

Calcium Oxalate Crystals

There are two types of calcium oxalate crystals. Bihydrated (or weddellite) crystals most often have a bipyramidal appearance ([Fig. 4.7B](#)); monohydrated (or whewellite) crystals are ovoid, dumbbell shaped, or biconcave disks ([Fig. 4.7C](#)). Both types of calcium oxalate crystals precipitate at pH 5.4 to 6.7. Monohydrated crystals always polarize light, whereas bihydrated crystals usually do not.

Calcium Phosphate Crystals and Amorphous Phosphates

Calcium phosphate crystals are pleomorphic, appearing as prisms, star-like particles, or needles of various sizes and shapes ([Fig. 4.7D](#)). They can also appear as plates with a granular surface. These crystals precipitate in alkaline urine (pH ≥ 7.0) and, with the exception of plates, polarize light intensely.

Amorphous phosphates are tiny particles identical to amorphous uric acids. However, they precipitate at a pH of 7.0 or higher and do not polarize light.

Triple Phosphate Crystals

These crystals contain magnesium ammonium phosphate and in most instances have the appearance of “coffin lids” ([Fig. 4.7E](#)). They are found in alkaline urine (pH ≥ 7.0), polarize light strongly, and suggest the presence of a urease-splitting bacterium.

Cholesterol Crystals

They are transparent and thin plates, often clumped together, with sharp edges ([Fig. 4.7F](#)).

Cystine Crystals

These crystals occur in patients with cystinuria and are hexagonal plates with irregular sides that are often heaped one on the other ([Fig. 4.7G](#)). They precipitate only in acid urine, especially after the addition of acetic acid and after overnight storage at 4°C. Evaluation of their size can be used to predict the recurrence of cystine stones.³⁸

2,8-Dihydroxyadenine Crystals

These are spherical, brownish crystals with radial striations from the center and polarize light strongly.^{39,40} They are a marker of homozygotic deficiency of the enzyme adenine phosphoribosyl-transferase. This rare condition causes crystalluria in about 96% of untreated patients, who frequently also suffer from radio-lucent urinary stone formation, AKI, or even chronic kidney disease.^{39,40}

Crystals Due to Drugs

Many drugs can cause crystalluria, especially in a setting of drug overdose, dehydration, or hypoalbuminemia in the presence of low urinary pH favoring drug crystallization. Examples include

Figure 4.7 Crystals. **A**, Uric acid crystals. This rhomboid shape is the most frequent. **B**, Bihydrated calcium oxalate crystals with their typical appearance of a “letter envelope.” **C**, Different types of monohydrated calcium oxalate crystals. **D**, A star-like calcium phosphate crystal.

the antibiotics sulfadiazine, amoxicillin (Fig 4.7H), and ciprofloxacin (Fig 4.7I)⁴¹; the antiviral agents acyclovir and indinavir (Fig. 4.7J); the vasodilators pyridoxylate and naftidrofuryl oxalate; the barbiturate primidone; the antiepileptic felbamate; the inhibitor of gastroenteric lipase orlistat; and intravenous vitamin C.³⁵

Whereas most of these drugs cause crystals with unusual appearances, naftidrofuryl oxalate, orlistat, and vitamin C cause calcium oxalate crystals.

Clinical Significance of Crystals

Uric acid, calcium oxalate, and calcium phosphate crystals are common and may be without clinical importance because they

can reflect transient supersaturation of the urine due to ingestion of some foods (e.g., meat for uric acid, spinach or chocolate for calcium oxalate, milk or cheese for calcium phosphate) or mild dehydration. However, the persistence of calcium oxalate or uric acid crystalluria may reflect hypercalciuria, hyperoxaluria, or hyperuricosuria. In calcium stone formers, crystalluria may be used to assess calcium stone disease activity.³⁷

Large numbers of uric acid crystals may be associated with AKI due to acute urate nephropathy, whereas large numbers of monohydrated calcium oxalate crystals, especially with a spindle shape, may be associated with AKI from ethylene glycol intoxication. Triple phosphate crystals are often associated with urinary

Figure 4.7, cont'd **E**, Triple phosphate crystal, on the background of a massive amount of amorphous phosphate particles. **F**, Cholesterol crystal. **G**, Cystine crystals heaped one on the other. **H**, Amoxicillin crystal resembling a branch of a broom bush.

Continued

tract infection caused by urea-splitting microorganisms such as *Ureaplasma urealyticum* and *Corynebacterium urealyticum*.

Some crystals are always pathologic. This is the case with cholesterol, which is found in patients with marked proteinuria; cystine, which is a marker of cystinuria; and 2,8-dihydroxyadenine.

When crystalluria is due to drugs, this may be the only urinary abnormality or it may be associated with hematuria, obstructive uropathy, or AKI due to the precipitation of crystals within the renal tubules. This last possibility has been described for almost all crystals due to drugs.³⁵

Organisms

Bacteria are a frequent finding because urine is usually collected and handled under nonsterile conditions and examination is often delayed. Urine infection can be suspected only if bacteria are found in noncontaminated, freshly voided midstream urine, especially if numerous leukocytes are also present.⁴²

Candida, *Trichomonas vaginalis*, and *Enterobius vermicularis* are mostly common contaminants derived from genital secretions.

Schistosoma haematobium is responsible for urinary schistosomiasis (see Chapter 54). In endemic areas, the examination of the

Figure 4.7, cont'd **I**, Star-like ciprofloxacin crystals as seen by polarized light. **J**, A large crystal of indinavir. (All images by phase contrast microscopy; original magnification $\times 400$.)

urinary sediment is the most widely used method for diagnosis of this condition, which causes recurrent bouts of macroscopic hematuria and obstructive uropathy. The diagnosis is based on the finding of the parasite eggs, with their typical terminal spike (Fig. 4.8). The eggs are especially found between 10 AM and 2 PM and after strenuous exercise.

Contaminants

A large number of particles can contaminate urine. These may come from the patient (e.g., spermatozoa, erythrocytes from menstruation, leukocytes from vaginitis, cloth or synthetic fibers, creams or talcum), the laboratory (e.g., starch particles, glass fragments from coverslips), or the environment (e.g., pollens, plant cells, fungal spores).³⁶ Correct identification of these particles is important to avoid misinterpretations and false results.

INTERPRETATION OF THE MAIN URINE SEDIMENT FINDINGS

Examination of the urine sediment, coupled with the quantity of proteinuria and other urine and blood findings, results in urine sediment profiles that aid in the diagnosis of urinary tract diseases (Fig. 4.9).

Nephrotic Sediment

The typical nephrotic sediment contains lipids, casts, and tubular cells. Hyaline, hyaline-granular, granular, and fatty casts are seen; erythrocyte or hemoglobin casts, leukocyte casts, and waxy casts are rare or absent. Erythrocytes may be totally absent, especially in minimal change disease, or may be in moderate numbers, for example, in membranous nephropathy and focal segmental glomerulosclerosis. Leukocytes are usually not found.

Figure 4.8 An egg of *Schistosoma haematobium*, containing the miracidium and with its typical terminal spike. (Phase contrast microscopy; original magnification $\times 400$.)

Main Urinary Sediment Profiles		
Renal Disease	Hallmark	Associated Findings
Nephrotic syndrome (proteinuria: +++)	Lipiduria Marked cylindruria	Renal tubular epithelial cells (RTECs) RTEC casts Microscopic hematuria: absent to moderate
Nephritic syndrome (proteinuria: + → +++)	Moderate to severe hematuria Erythrocyte/hemoglobin casts	Mild leukocyturia RTECs (low number) RTEC casts Waxy casts
Acute kidney injury (proteinuria: absent to trace)	RTECs either normal or damaged/necrotic RTEC casts Granular casts	Variable according to the cause of ATN (e.g., pigmented myoglobin casts in rhabdomyolysis; uric acid crystals in acute urate nephropathy)
Urinary tract infection (proteinuria: absent)	Bacteria Leukocytes	Superficial transitional epithelial cells Isomorphic erythrocytes Triple phosphate crystals (for infections due to urease-producing bacteria) Leukocyte casts (in renal infection)
Polyomavirus BK infection (proteinuria: absent)	Decoy cells	Macrophages

Figure 4.9 Main urinary sediment profiles. ATN, acute tubular necrosis.

Nephritic Sediment

Hematuria is the hallmark of the nephritic sediment. More than 100 erythrocytes per high-power field is not uncommon, especially in cases with extracapillary or necrotizing glomerular lesions. Mild leukocyturia is also frequent. Erythrocyte and hemoglobin casts are frequent. Leukocyte and waxy casts can also be observed.

The nephritic sediment may clear with treatment, but its reappearance usually indicates relapse of the disease, such as lupus nephritis⁴³ or systemic vasculitis.⁴⁴ In rare cases, there may be an active proliferative GN without a nephritic sediment.

In our experience, it is possible to distinguish proliferative from nonproliferative GN by the examination of the urine sediment with 80% sensitivity and 79% specificity. Proliferative GN is associated with higher numbers of erythrocytes, leukocytes, and tubular epithelial cells as well as with erythrocyte and epithelial cell casts.³¹

Sediment of Acute Kidney Injury

In AKI, the urine sediment contains variable numbers of renal tubular cells, either normal or damaged or necrotic, and a marked granular and epithelial cylindruria.⁴⁵ In addition, depending on the cause of the tubular damage, other elements can be seen. For instance, in rhabdomyolysis, myoglobin pigmented casts are found; in AKI due to intratubular precipitation of crystals (e.g., acute uric acid nephropathy, ethylene glycol poisoning, drugs), there may be massive crystalluria.

Sediment of Urinary Tract Infection

Bacteriuria and leukocyturia are the hallmarks of urinary tract infection, and superficial uroepithelial cells and isomorphic erythrocytes are common. Triple phosphate crystals are also

present when the infection is caused by urease-producing bacteria, such as *U. urealyticum* or *C. urealyticum*. In the case of renal infection, leukocyte casts may be found.

The correlation between the urine sediment findings and the urine culture is usually good. False-positive results may occur as a consequence of urine contamination from genital secretions or bacterial overgrowth on standing. False-negative results may be due to misinterpretation of bacteria (especially with cocci) or the lysis of leukocytes.

BK Virus Infection

In this condition (see Chapter 101), the urinary sediment contains variable numbers of decoy cells. These are renal tubular cells with nuclear changes due to the cytopathic effect of the virus. There is nuclear enlargement (“ground glass appearance”), chromatin margination, abnormal chromatin patterns, and viral inclusion bodies of various sizes and shapes with or without a perinuclear halo. As a general rule, the higher the number, the more severe the infection. These cells can be seen by phase contrast microscopy in unstained samples (Fig. 4.10A),⁴⁶ even though they are usually identified by cytocentrifuged smears with the Papanicolaou stain (Fig. 4.10B).⁴⁷ Electron microscopy shows virus particles with mean diameter of 45 Å (Fig. 4.10C). In addition to decoy cells, macrophages are frequent and abundant. The finding of decoy cells in the urine is sufficient to diagnose reactivation of the viral infection; for the diagnosis of BK virus nephropathy, a renal biopsy is mandatory.

Nonspecific Urinary Abnormalities

Some urine sediments are less specific, such as variable numbers of nonspecific casts with or without mild erythrocyturia or leukocyturia, mild crystalluria, and small numbers of superficial

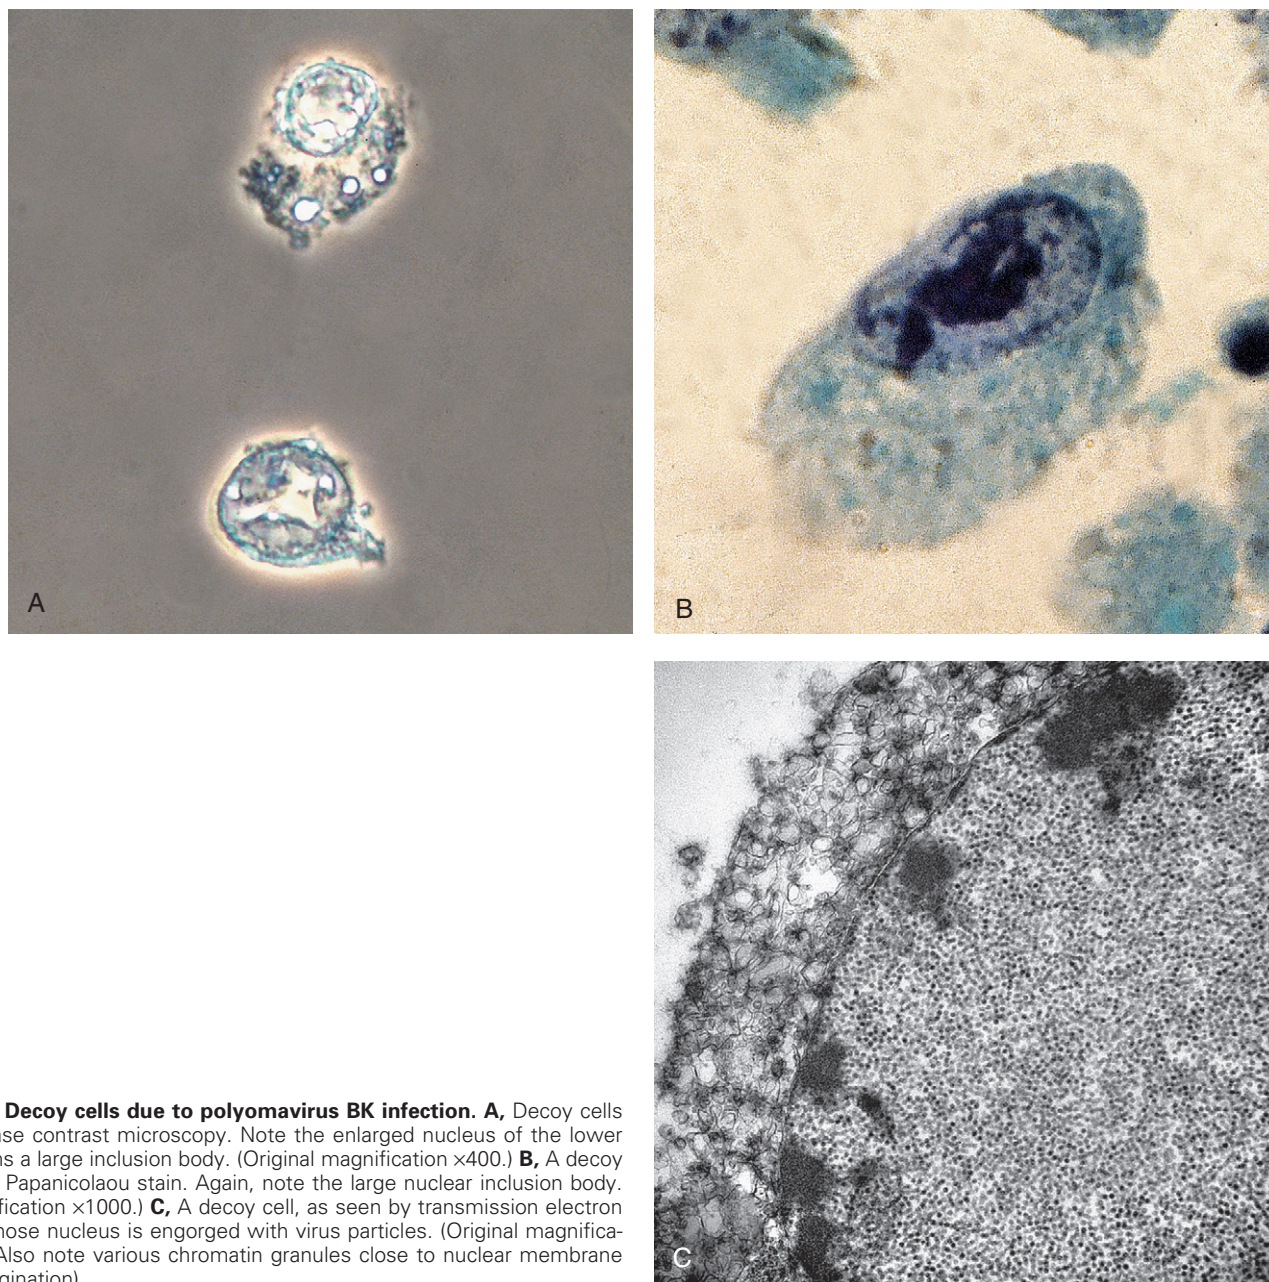

Figure 4.10 Decoy cells due to polyomavirus BK infection. **A**, Decoy cells as seen by phase contrast microscopy. Note the enlarged nucleus of the lower cell that contains a large inclusion body. (Original magnification $\times 400$.) **B**, A decoy cell as seen by Papanicolaou stain. Again, note the large nuclear inclusion body. (Original magnification $\times 1000$.) **C**, A decoy cell, as seen by transmission electron microscopy, whose nucleus is engorged with virus particles. (Original magnification $\times 30,000$.) Also note various chromatin granules close to nuclear membrane (chromatin margination).

epithelial cells. In such cases, the correct interpretation of the urinary findings requires adequate clinical information and possibly renal biopsy.

AUTOMATED ANALYSIS OF THE URINE SEDIMENT

Instruments for the automated analysis of the urinary sediment are now available. These are based on flow cytometry or digital imaging. Flow cytometry uses stains for nucleic acid and cell membranes in uncentrifuged urine samples and so identifies cells, bacteria, and casts.⁴⁸ Accuracy is good for leukocytes and erythrocytes, even though the erythrocytes can be overestimated because of the interference from bacteria, crystals, and yeasts.

As to casts, false-negative results are frequent, ranging from about 13% to 43%. Digital imaging systems supply black and white images of urine particles. Precision and accuracy are good for erythrocytes and leukocytes, but sensitivity for casts is relatively low.⁴⁹

Today, automated instruments are used especially in large laboratories to screen large numbers of samples in a short time and to identify the samples that are normal or contain only minor changes. This approach greatly reduces the number of samples that require manual microscopy. However, these instruments do not recognize lipids, cannot distinguish between uroepithelial cells and renal tubular cells, and do not identify various types of casts and crystals, some of which are clinically important. Therefore, they cannot yet be used alone for the evaluation of the renal patient.

Imaging

David C. Wymer

DEFINITION

In recent years, there has been a significant change in imaging evaluation of patients with renal disease. Intravenous urography (IVU) is infrequently used and has mostly been replaced by ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine scanning. There are major technologic advances in each of these modalities with the rapid changes in computer-based data manipulation. Three-dimensional and even four-dimensional (time-sensitive) image analysis is now available. “Molecular” imaging, in which biomarkers are used to visualize cellular function, is beginning to provide functional as well as anatomic information.

The American College of Radiology has published Appropriateness Criteria,¹ guidelines that suggest the choice of imaging to provide a rapid answer to the clinical question while minimizing cost and potential adverse effects to the patient, such as contrast-induced nephrotoxicity and radiation exposure. Relative radiation exposures are shown in [Figure 5.1](#). First-choice imaging techniques in selected clinical scenarios are shown in [Figure 5.2](#). Risks of imaging ([Fig. 5.3](#)) and cost need to be balanced against benefits.

ULTRASOUND

Ultrasound is relatively inexpensive and provides a rapid way to assess renal location, contour, and size without radiation exposure. Nephrologists are increasingly undertaking straightforward ultrasound examination; the practical techniques as well as the appropriate interpretative skills are discussed in Chapter 88. Portable ultrasound is available and is essential in the pediatric or emergency setting. Obstructing renal calculi can be readily detected, and renal masses can be identified as cystic or solid. In cases of suspected obstruction, the progression or regression of hydronephrosis is easily evaluated. Color Doppler imaging permits assessment of renal vascularity and perfusion. Unlike the other imaging modalities, ultrasound is highly dependent on operator skills. Limitations of ultrasound include lack of an acoustic window, body habitus, and poor cooperation of the patient.

Kidney Size

The kidney is imaged in transverse and sagittal planes and is normally 9 to 12 cm in length in adults. Differences in renal size can be detected with all imaging modalities. The common causes of enlarged and shrunken kidneys are shown in [Figure 5.4](#).

Renal Echo Pattern

The normal cortex is hypoechoic compared with the fat-containing echogenic renal sinus ([Fig. 5.5A](#)). The cortical

echotexture is defined as isoechoic or hypoechoic compared with the liver or spleen. In children, the renal pyramids are hypoechoic ([Fig. 5.5B](#)), and the cortex is characteristically hyperechoic compared with the liver and the spleen.² In adults, an increase in cortical echogenicity is a sensitive marker for parenchymal renal disease but is nonspecific ([Fig. 5.6](#)). Decreased cortical echogenicity can be found in acute pyelonephritis and acute renal vein thrombosis.

The normal renal contour is smooth, and the cortical mantle should be uniform and slightly thicker toward the poles. Two common benign pseudomasses that can be seen with ultrasound are the dromedary hump and the column of Bertin. The column of Bertin results from bulging of cortical tissue into the medulla; it is seen as a mass with an echotexture similar to that of the cortex, but it is found within the central renal sinus ([Fig. 5.7](#)). The renal pelvis and proximal ureter are anechoic. An extrarenal pelvis refers to the renal pelvis location outside the renal hilum. The ureter is not identified beyond the pelvis in nonobstructed patients.

Obstruction can be identified by the presence of hydronephrosis ([Fig. 5.8](#)). Parenchymal and pelvicalyceal nonobstructing renal calculi as well as ureteral obstructing calculi can be readily detected ([Fig. 5.9](#)). The upper ureter will also be dilated if obstruction is distal to the pelviureteral junction (see [Fig. 5.8C](#)). False-negative ultrasound examination findings with no hydronephrosis occasionally occur in early obstruction. Obstruction without ureteral dilation may also occur in retroperitoneal fibrosis and in transplanted kidneys as a result of periureteral fibrosis.

Renal Cysts

Cysts can be identified as anechoic lesions and are a frequent coincidental finding during renal imaging. Ultrasound usually readily identifies renal masses as cystic or solid ([Figs. 5.10 and 5.11](#)). However, hemorrhagic cysts can sometimes be mistakenly called solid because of increased echogenicity. Differentiation of cysts as simple or complex is required to plan intervention.

Simple Cysts

A simple cyst on ultrasound is anechoic, has a thin or imperceptible wall, and demonstrates through-transmission because of the relatively rapid progression of the sound wave through fluid compared with adjacent soft tissue.

Complex Cysts

Complex cysts contain calcifications, septations, and mural nodules. Instead of being anechoic, they may contain internal echoes representing hemorrhage, pus, or protein. Complex cysts may be benign or malignant; malignancy is strongly suggested

Relative Radiation Doses of Imaging Examinations	
Examination	Effective Dose (mSv)
Chest (PA film)	0.02
Lumbar spine	1.8
KUB (abdomen)	0.53
CT abdomen	10
CT chest	20–40
PET–CT	25
Ultrasound or MRI	0

Figure 5.1 Relative radiation doses of imaging examinations. KUB, kidney-ureter-bladder.

Suggested Imaging in Renal Disease	
AKI or CKD	Ultrasound
Hematuria	Ultrasound or CT
Proteinuria, nephrotic syndrome	CT urography Ultrasound
Hypertension with normal renal function	Ultrasound Consider CT angiography or MR angiography
Hypertension with impaired renal function	Ultrasound with Doppler
Renal infection	CECT
Hydronephrosis seen by ultrasound	Nuclear renogram
Retroperitoneal fibrosis	CECT
Papillary or cortical necrosis	CECT
Renal vein thrombosis	CECT
Renal infarction	CECT
Nephrocalcinosis	CT

Figure 5.2 Suggested imaging in renal disease. These recommendations assume availability of all common imaging modalities. CT, computed tomography; MR, magnetic resonance; CECT, contrast enhanced CT. (Modified from Appropriateness Criteria of the American College of Radiology.¹)

by cyst wall nodularity, septations, and vascularity. Complex cysts identified by ultrasound require further evaluation by contrast-enhanced CT (or MRI) to identify abnormal contrast enhancement of the cyst wall, mural nodule, or septum.

Bladder

Real-time imaging can be used to evaluate for bladder wall tumors and bladder stones. Color flow Doppler evaluation of the bladder in well-hydrated patients can be used to identify a ureteral jet. The jet is produced when peristalsis propels urine into the bladder, the incoming urine having a specific gravity higher

Risk Estimates in Diagnostic Imaging	
Cancer from 10 mSv of radiation (1 body CT) ³	1 in 1000
Contrast-induced nephropathy in patient with renal impairment ⁴	1 in 5
Nephrogenic systemic fibrosis ^{5,6}	1 in 25,000 to 30,000 (depends on gadolinium agent)
Death from iodine contrast anaphylaxis ⁷	1 in 130,000
Death from gadolinium contrast anaphylaxis ⁸	1 in 280,000

Figure 5.3 Risk estimates in diagnostic imaging. (Modified from references 3–8.)

relative to the urine already in the bladder (Fig. 5.12). Absence of the ureteral jet can indicate total ureteral obstruction.

Renal Vasculature

Color Doppler investigation of the kidneys provides a detailed evaluation of the renal vascular anatomy. The main renal arteries can be identified in most patients (Fig. 5.13). Power Doppler imaging is a more sensitive indicator of flow, but unlike color Doppler imaging, it does not provide any information about flow direction, and it cannot be used to assess vascular waveforms. It is, however, exquisitely sensitive for detection of renal parenchymal flow and has been used to identify cortical infarction.

Renal Artery Duplex Scanning

The role of gray-scale and color Doppler sonography in screening for renal artery stenosis is controversial.

The principle is that a narrowing in the artery will cause a velocity change commensurate with the degree of stenosis as well as a change in the normal renal arterial waveform downstream from the lesion. The normal renal arterial waveform demonstrates a rapid systolic upstroke and an early systolic peak (Fig. 5.14A). The waveform becomes dampened downstream from a stenosis. This consists of a slow systolic acceleration (tardus) and a decreased and rounded systolic peak (parvus; Fig. 5.14B). It also results in a decrease in the resistive index, defined as the end-diastolic velocity [EDV] subtracted from the peak systolic velocity [PSV] divided by PSV [(PSV – EDV)/PSV]. The normal resistive index is 0.70 to 0.72.

The entire length of the renal artery should be examined for the highest velocity signal. The origins of the renal arteries are important to identify because this is a common area affected by atherosclerosis, but they are often difficult to visualize because of overlying bowel gas. Within the kidney, medullary branches and cortical branches in the upper, middle, and lower thirds should be included to attempt detection of stenosis in accessory or branch renal arteries.

There are proximal and distal criteria for diagnosis of significant renal artery stenosis (usually defined as stenosis >60%). The proximal criteria detect changes in the Doppler signal at the site of stenosis and provide sensitivities and specificities ranging from 0% to 98% and 37% to 98%, respectively.^{9,10} Technical failure rates are typically 10% to 20%.¹¹ Renal artery stenosis may also

Figure 5.4 Common causes of abnormal renal size.

Figure 5.7 **Sagittal renal ultrasound image.** Column of Bertin is present (arrows) and is easily identified because of echotexture similar to that of the cortex.

Figure 5.8 Renal ultrasound study demonstrating hydronephrosis. **A**, Sagittal image. **B**, Transverse image. **C**, Transverse three-dimensional surface-rendered image; arrows indicate the dilated proximal ureter.

be missed if PSV is low because of poor cardiac output or aortic stenosis. False-positive results can occur when renal artery velocity is increased because of high-flow states, such as hyperthyroidism or vessel tortuosity.¹² The distal criteria are related to detection of a tardus-parvus waveform distal to a stenosis; sensitivities and specificities of 66% to 100% and 67% to 94%, respectively, have been reported.^{13,14} Technical failure is much lower than with proximal evaluation (<5%). False-negative results can occur from stiff poststenotic vessels, which will decrease the tardus-parvus effect.¹⁵ The tardus-parvus effect may also be a result of aortic stenosis, low cardiac output, or collaterals in complete occlusion giving a false-positive result.

Figure 5.9 Sagittal ultrasound image showing an upper pole renal calculus (arrow). Note the acoustic shadowing (arrowhead).

Figure 5.10 Evaluation of a renal mass. **A**, Sagittal ultrasound image showing a large hyperechoic mass arising from the lower pole (arrows). **B**, Corresponding contrast-enhanced CT scan showing a renal cell carcinoma (arrow).

Combining the proximal and distal criteria improves the detection of stenoses. Sensitivity of 97% and specificity of 98% can be achieved when both the extrarenal and intrarenal arteries are examined.¹⁶ When it is technically successful, Doppler ultrasound has a negative predictive value of more than 90%.¹⁶ However, reliable results require a skilled and experienced sonographer and a long examination time. Notwithstanding these limitations,

Figure 5.11 Sagittal renal ultrasound image showing a complex cyst (arrows).

Figure 5.12 Bilateral ureteral jets in the bladder detected with color Doppler ultrasound study. This is a normal appearance.

Figure 5.13 Transverse color Doppler ultrasound evaluation of the kidney. The artery is shown as red, the vein as blue.

Doppler studies also have several advantages. These studies are noninvasive, inexpensive, and widely available, and they allow structural and functional assessment of the renal arteries and image without exposure to radiation or nephrotoxic agents.

CT angiography (CTA) or magnetic resonance angiography (MRA) is preferred by some as a faster and more reliable screening tool, but at present, the choice should depend on local expertise and preference. For further discussion of the diagnosis and management of renovascular disease, see Chapters 37 and 64.

Figure 5.14 Renal artery color Doppler image and spectral tracing. **A**, Normal renal arterial tracing showing the rapid systolic upstroke and early systolic peak velocity (~100 cm/s). **B**, Tardus-parvus waveform demonstrating the slow systolic upstroke (acceleration) and decreased peak systolic velocity (~20 cm/s) associated with renal artery stenosis. Note different scales on vertical axis.

Contrast-Enhanced and Three-Dimensional Ultrasound

Ultrasound contrast agents, initially introduced to assess cardiac perfusion, are now being used to evaluate perfusion to other organs, such as the kidney. These intravenous agents are microbubbles that consist of a shell surrounding the echo-producing gas core; they are 1 to 4 μm in diameter, smaller than erythrocytes. The microbubbles oscillate in response to the ultrasound beam frequency and give a characteristic increased echo signal on the image. Preliminary studies evaluating renal perfusion in dysfunctional kidneys show reduced flow compared with normal kidneys and improved lesion detection (Fig. 5.15). However the clinical utility of microbubble imaging in the kidney remains uncertain, particularly given the general availability and robustness of CT and MRI.

Two-dimensional ultrasound images can be reconstructed into three-dimensional volume images by a process similar to three-dimensional reconstructions for MRI and CT. Although the current techniques are time-consuming, technical improvements should decrease reconstruction time. Potential applications include vascular imaging and fusion with MRI or positron emission tomography (PET).

PLAIN RADIOGRAPHY AND INTRAVENOUS UROGRAPHY

The use of IVU has receded as cross-sectional imaging by CT or MRI has become more widely applied to the urinary tract. Contrast urography now has few primary indications in many centers, but it may still be a key investigation in parts of the world where economic limitations mean that cross-sectional imaging is not available. However, plain radiography (often called a KUB—kidneys, ureter, bladder), still has an important role in the identification of soft tissue masses, bowel gas pattern, calcifications, and renal location.

Figure 5.15 Contrast ultrasonography. **A**, Sagittal renal ultrasound image with a large central renal cell cancer (arrows). **B**, Central cancer better seen after injection of contrast material. (Courtesy of Dr. Christoph F. Dietrich.)

Renal Calcification

Most renal calculi are radiodense, although only ~60% of urinary stones detected on CT are visible on plain films.¹⁷ CT demonstrates nonopaque stones, which include uric acid, xanthine, and struvite stones. However, neither CT nor plain films may detect calculi associated with protease inhibitor therapy.¹⁸ Oblique films are sometimes obtained to confirm whether a suspicious upper quadrant calcification is renal in origin. Calculi that are radiolucent on plain films are usually detected as filling defects on IVU. Although IVU has a higher sensitivity compared with plain films, the sensitivity is lower compared with CT, which, if it is available, is the imaging modality of choice for detection of urinary calculi.¹⁹

Nephrocalcinosis may be medullary (Fig. 5.16A, B) or cortical (Fig. 5.16C) and is localized or diffuse. The common causes of nephrocalcinosis are shown in Figure 57.17.

Intravenous Contrast Urography

Before contrast material is administered, an abdominal compression device may be placed. It is placed to compress the mid ureters against the bony pelvis, retaining the excreted contrast material in the upper tract and distending the renal pelvis and calyces. The first film is usually performed at 30 seconds after injection of the contrast agent, when the renal parenchyma is at peak enhancement. Subtle renal masses are often detected only

Figure 5.16 Nephrocalcinosis. **A**, Plain film showing bilateral medullary nephrocalcinosis in a patient with distal renal tubular acidosis. **B**, Non-contrast-enhanced CT scan in a patient with hereditary oxalosis and dense bilateral renal calcification (arrows). The left kidney is atrophic. **C**, Non-contrast-enhanced CT scan showing cortical nephrocalcinosis in the right kidney (arrows) after cortical necrosis.

on these early films. The compression device is then removed, and films of the entire abdomen are obtained at 5 minutes, when there is renal excretion of the contrast agent and the ureters are best evaluated. Prone films may be required to visualize the entirety of the ureter. A filled bladder film is obtained, and a postvoid film of the bladder assesses bladder emptying and is useful for evaluation of the distal ureters, which may be obscured by a distended contrast-filled bladder. IVU is contraindicated in patients with a history of allergic reactions to radiographic contrast agents. When the glomerular filtration rate (GFR) is below 60 ml/min, IVU yields increasingly poor images, and the risk of nephrotoxicity also increases.

Kidneys

Evaluation of the kidneys on IVU (and also on CT or MRI) should include their number, location, axis, size, contour, and degree of enhancement. Renal size is variable, but a normal kidney should be about three to four lumbar vertebral bodies in length. The renal outline should be smooth and sharply demarcated from the retroperitoneal fat. Renal enhancement after the administration of contrast material should be symmetric and progress centrally from the cortex, with excretion evident in the ureters by 5 minutes. Asymmetry of renal enhancement can be indicative of renal arterial disease.

Pelviccalyceal System

The pelviccalyceal system is best evaluated on the early postcontrast films. Normally, there are about 10 to 12 calyces per kidney. The calyces drain into the infundibula, which in turn empty into the renal pelvis (Fig. 5.17). The infundibulum and renal pelvis should have smooth contours without filling defects. There is a common variant wherein vessels can cross the pelviccalyceal system or ureters, causing extrinsic compression defects that should not be mistaken for tumors or other urothelial lesions. When more than one calyx drains into an infundibulum, it is known as a compound calyx, most frequently seen in the poles. The normal calyx is gently cupped. Calyceal distortion occurs with papillary necrosis and reflux nephropathy.

Figure 5.17 Normal parenchymal enhancement and normal renal excretion. Early postcontrast tomogram in intravenous urography.

Ureters

The ureters are often seen segmentally because of active peristalsis. The ureters should be free of filling defects and smooth. In the abdomen, the ureters lie in the retroperitoneum, passing anterior to the transverse processes of the vertebral bodies. In the pelvis, the ureters course laterally and posteriorly, eventually draining into the posteriorly located vesicoureteral junction. At the vesicoureteral junction, the ureters gently taper. Medial bowing or displacement of the ureter is often abnormal and can be seen secondary to ureter displacement from retroperitoneal masses, lymphadenopathy, and retroperitoneal fibrosis.

Bladder

The bladder should be rounded and smooth walled. Benign indentations on the bladder include the uterus, prostate gland, and bowel. In chronic bladder outlet obstruction and neurogenic bladder, there can be numerous trabeculations and diverticula around the bladder outline.

RETROGRADE PYELOGRAPHY

Retrograde pyelography is performed when the ureters are poorly visualized on other imaging studies or when samples of urine need to be obtained from the kidney for cytology or culture. Patients who have severe allergies to contrast agents or impaired renal function can be evaluated with retrograde pyelography. The examination is performed by placing a catheter through the ureteral orifice under cystoscopic guidance and advancing it into the renal pelvis. With use of fluoroscopy, the catheter is slowly withdrawn while radiographic contrast material is injected (see Figs. 58.4 and 58.13). This technique provides excellent visualization of the renal pelvis and ureter and can be used for cytologic sampling from suspect areas.

ANTEGRADE PYELOGRAPHY

Antegrade pyelography is performed through a percutaneous renal puncture and is resorted to when retrograde pyelography is not possible. Ureteral pressures can be measured, hydronephrosis evaluated, and ureteral lesions identified (see Fig. 58.16). The examination is often performed as a prelude to nephrostomy placement. Both antegrade and retrograde pyelography are invasive and should be performed only when other studies are inadequate.

ILEAL CONDUITS

After cystectomy, or bladder failure, there are numerous types of continent or incontinent urinary diversions that can be surgically created. One of the most common diversions is the ileal conduit: an ileal loop is isolated from the small bowel, and the ureters are implanted into the loop. This end of the loop is closed, and the other end exits through the anterior abdominal wall. This type of conduit can be evaluated by an excretory study or a retrograde study. The excretory or antegrade study is performed and monitored in the same way as an IVU. A retrograde examination, also referred to as a loop-o-gram, is obtained when the ureters and conduit are suboptimally evaluated on the excretory study. A Foley catheter is placed into the stoma, and contrast material is then slowly instilled. The ureters should fill by reflux

Figure 5.18 Imaging of an ileal conduit. **A**, Loop-o-gram. A recurrent transitional carcinoma is present in the reimplanted left ureter (arrow). **B**, CT scan clearly showing the tumor as a filling defect in the anterior aspect of the opacified ureter (arrow).

because the ureteral anastomoses are not of the antireflux variety (Fig. 5.18).

CYSTOGRAPHY

A cystogram is obtained when more detailed radiographic evaluation of the bladder is required. Voiding cystography is performed to identify ureteral reflux and to assess bladder function and urethral anatomy. A urethral catheter is placed into the bladder, and the urine is drained; contrast material is infused, and the bladder is filled under fluoroscopic guidance. Early supine frontal and oblique films are obtained while the bladder is filling. Ureteroceles are best identified on early films. When the bladder is full, multiple films are obtained with varying degrees of obliquity. Reflux may be seen on these films. To obtain a voiding cystogram, the catheter is removed, and the patient voids. The contrast material is followed into the urethra. On occasion, bladder diverticula are seen only on the voiding films. When the patient has completely voided, a final film is used to assess the amount of residual urine as well as the mucosal pattern. Radionuclide cystography is an alternative often used in children. It is useful in the diagnosis of reflux, but it does not provide the detailed anatomy that is seen with contrast cystography.

Figure 5.19 CT scan showing bilateral pelvic kidneys (arrows).

Figure 5.20 CT scan showing normal renal transplant (arrows).

COMPUTED TOMOGRAPHY

CT examination of the kidneys is performed to evaluate suspect renal masses, to locate ectopic kidneys (Figs. 5.19 and 5.20), to investigate calculi, to assess retroperitoneal masses, and to evaluate the extent of parenchymal involvement in patients with acute pyelonephritis (Figs. 5.21 and 22). Helical CT scanners allow the abdomen and pelvis to be scanned at 3- to 5-mm intervals with one or two breath-held acquisitions, which eliminates motion artifact. Newer multidetector row CT results in multiple slices of information (currently 64-slice and now even 320-slice machines are becoming commonplace) being acquired simultaneously, allowing the entire abdomen and pelvis to be covered in one breath-hold, using even submillimeter intervals. However, the improved CT imaging comes at a price of significant radiation exposure to the patient. The CT data can be reconstructed in multiple planes and even in three dimensions for improved anatomic visualization and localization.

Tissue Density

The Hounsfield unit (HU) scale is a measurement of relative densities determined by CT. Distilled water at standard pressure and temperature is defined as 0 HU; the radiodensity of air is defined as -1000 HU. All other tissue densities are derived from this (Fig. 5.23). Tissues can vary in their exact HU measurements and will also change with contrast enhancement. Water, fat, and soft tissue can often look identical on the scan, depending on the window and level settings of the image, so actual HU measurement is essential to correctly characterize the tissues.

Figure 5.21 Emphysematous pyelonephritis. Contrast-enhanced CT scan showing gas (arrowheads) within an enlarged left kidney and marked enhancement of Gerota's fascia (G) and the posterior perirenal space (P) indicative of inflammatory involvement.

Figure 5.22 Acute pyelonephritis. A, Ultrasound image demonstrates an enlarged echogenic kidney. Bipolar length of kidney is 12.9 cm. B, CT scan with contrast enhancement obtained 24 hours later demonstrates multiple nonenhancing abscesses (arrows).

Contrast-Enhanced and Noncontrast Computed Tomography

CT examination of the kidneys can be performed with or without intravenous administration of contrast material. Noncontrast imaging allows the kidneys to be evaluated for the presence of calcium deposition and hemorrhage, which are obscured after the administration of contrast material.

The Density of Common Substances Determined by CT

Substance	HU
Air	-1000
Fat	-120
Water	0
Muscle	+40
Bone	+400 or more

The Hounsfield unit (HU) scale is a measurement of relative densities compared with distilled water.

Figure 5.23 The density of common substances determined by CT.

Figure 5.24 Computer-reformatted, volume-rendered CT urogram obtained from axial CT acquisition.

Noncontrast CT (CT urography, CTU) is the examination of choice in patients with suspected nephrolithiasis and has replaced the KUB and intravenous urography in most situations.^{20,21} The study consists of unenhanced images from the kidneys through the bladder for detection of calculi (Fig. 5.24). CTU has the advantage of being both highly sensitive (97% to 100%) and specific (94% to 96%) for diagnosis of urinary calculi.^{19,22} It can identify a possible obstructing calculus as well as the extent of parenchymal and perinephric involvement.

In cases other than stone evaluation, the kidneys are imaged after the administration of contrast material. The kidneys are imaged in the corticomedullary phase for evaluation of the renal vasculature as well as in the nephrographic phase

Figure 5.25 Delayed excretion in the left kidney secondary to a distal calculus. Contrast-enhanced CT scan showing dilated left renal pelvis (arrows).

for evaluation of the renal parenchyma. The degree of enhancement can be assessed in both solid masses and complex cysts (see Fig. 58.11).

A compression device can be used as in IVU. Delayed images through the kidneys and bladder are performed for evaluation of the opacified and distended collecting system, ureters, and bladder.^{23,24} Once the axial images have been obtained, they can be reformatted into coronal or sagittal planes to optimize visualization of the entire collecting system. The study can be tailored to the individual clinical scenario. For example, the corticomedullary phase can be eliminated to decrease the radiation dose if there is no concern about a vascular abnormality or no need for presurgical planning. A diuretic or saline bolus can be administered after the contrast agent to better distend the collecting system and ureters during the excretory phase.

The kidneys should be similar in size and show equivalent enhancement and excretion. During the cortical medullary phase, there is brisk enhancement of the cortex. The cortical mantle should be intact. Any disruption of the cortical enhancement requires further evaluation; it may be caused by acute pyelonephritis (see Fig. 5.22), scarring, mass lesions, or infarction (Fig. 5.26). During the excretory phase, the entire kidney and renal pelvis enhance. Delayed excretion and delay in pelvicalyceal appearance of contrast material can be findings in obstruction (see Fig. 5.25) but also in renal parenchymal disease such as acute tubular necrosis.

Computed Tomographic Angiography

Helical scanning facilitates CTA, which can produce images that are similar to those of conventional angiography, but it is less invasive. A bolus of contrast material is administered, and the images are obtained at 0.5- to 3-mm consecutive intervals. The contrast bolus is timed for optimal enhancement of the aorta. Thinner collimation of the CT beam allows higher resolution and better subsequent multiplanar reconstructions. The aorta and branch vessels are well demonstrated (Fig. 5.27). This technique is now widely used in living transplant donor evaluation (see Fig. 99.2), providing information not only on arterial and venous anatomy but also on size, number, and location of the kidneys as well as any ureteral anomalies of number or position.

CTA can also be used to screen for atheromatous renal artery stenosis, with sensitivity of 96% and specificity of 99% for the

Figure 5.26 Renal infarction involving the medial half of the right kidney after aortic bypass surgery. CT scan shows densely calcified wall of the native aorta (arrow). The aortic graft is anterior to the native aorta (arrowhead).

Figure 5.27 Three-dimensional reformatted CT angiogram of the normal renal arteries.

detection of hemodynamically significant stenosis compared with digital subtraction angiography.²⁵ Furthermore, CTA allows visualization of both the arterial wall and lumen, which helps in the planning of renal artery revascularization procedures. Another advantage of CTA is the depiction of accessory renal arteries as well as nonrenal causes of hypertension, such as adrenal masses. CTA can be used to diagnose fibromuscular dysplasia, but it has a much lower sensitivity (87%) than digital subtraction angiography.²⁶

Limitations of Computed Tomography

There are some limitations of CT. The cradle that the patient lies on usually has an upper weight limit of 100 to 200 kg (300 to 400 pounds), but newer scanners can now accommodate up to 270 kg (600 pounds). Obese patients often have suboptimal scans because of weight artifact and need higher radiation exposures to adjust for x-ray attenuation. Contrast-enhanced CT studies are contraindicated in patients with an allergy to radiographic contrast dye and in patients with impaired renal function. To minimize contrast-induced nephropathy, contrast material should not be given to patients with GFR below 30 ml/min without carefully weighing the risks and benefits, and it should be used with caution with GFR of 30 to 60 ml/min.

CT is very sensitive to metal artifact and motion of the patient. Retroperitoneal clips and intramedullary rods will cause extensive streak artifact, which severely degrades the images. Patients who are unable to remain motionless will also have

suboptimal or even nondiagnostic studies, and sometimes sedation or general anesthesia may be needed to obtain diagnostic scans, particularly in children. Intensive care unit and critically ill patients can be scanned by CT as long as they are stable enough to be transported to the CT suite. Ultrasound should be entertained as an alternative to CT in the seriously ill patient who cannot be safely transported.

MAGNETIC RESONANCE IMAGING

MRI should only rarely be the first examination used to evaluate the kidneys, but it is typically an adjunct to another imaging technique. The major advantage of MRI over the other imaging modalities is direct multiplanar imaging, whereas CT is limited to slice acquisition in the axial plane of the abdomen, and coronal and sagittal planes are acquired only by reconstruction, which can lead to loss of information.

Tissues contain an abundance of hydrogen, the nuclei of which are positively charged protons. These protons spin on their axis, producing a magnetic field (magnetic moment). When a patient is placed in a strong magnetic field in an MRI scanner, some of the protons align themselves with the field. When a radiofrequency pulse is applied, some of the protons aligned with the field will absorb energy and reverse their direction. This absorbed energy is given off as a radiofrequency pulse as the protons relax (return to their original alignment), producing a voltage in the receiver coil. The coil is the hardware that covers the region of interest. For renal imaging, a body coil or torso coil is used. Relaxation is a three-dimensional event giving rise to two parameters: T1 relaxation results in the recovery of magnetization in the longitudinal (spin-lattice) plane, whereas T2 results from the loss of transverse (spin-spin) magnetization. A rapid-sequence variant of T2 in common use is fast spin echo (FSE). Hydrogen ions move at slightly different rates in the different tissues. This difference is used to select imaging parameters that can suppress or aid in the detection of fat and water. Fluid, such as urine, is dark or low in signal on T1-weighted sequences and bright or high in signal on FSE sequences. Fat is bright on T1 and not as bright on FSE sequences (Fig. 5.28). The sequences and imaging planes selected must be tailored to the individual case. Diffusion-weighted imaging is a newer technique that evaluates the freedom of water molecules to diffuse in tissues; restriction of diffusion is imaged as bright areas on the scan and is seen in infection, neoplasia, inflammation, and ischemia.

Standard imaging usually includes T1, T2, or FSE sequences and often additional contrast-enhanced T1 images. The imaging plane varies according to the clinical concerns. Usually, at least one sequence is performed in the axial plane. Sagittal and coronal images cover the entire length of the kidney and can make some subtle renal parenchymal abnormalities more conspicuous (Fig. 5.29).

On T1-weighted sequences, the normal renal cortex is higher in signal than the medulla, producing a distinct corticomedullary differentiation, which becomes indistinct in parenchymal renal disease. It is analogous to the echogenic kidney seen on ultrasound. On FSE sequences, the corticomedullary distinction is not as sharp but should still be present.

Contrast-Enhanced Magnetic Resonance Imaging

As with CT, intravenous contrast material can be administered to allow further characterization of renal lesions. Gadolinium is a paramagnetic contrast agent that is frequently used in MRI and

Figure 5.28 Magnetic resonance imaging of tuberous sclerosis. There are multiple renal angiomyolipomas. **A**, T1-weighted image. The tumors are high in signal on T1 because of their fat; the arrow shows the largest. **B**, T1-weighted image with fat suppression. The fat within the tumors is now low in signal (arrow).

is much less nephrotoxic than iodinated contrast material.²⁷ Adverse reactions to gadolinium are discussed later (see [Magnetic Resonance Contrast Agents](#)). Paramagnetic contrast agents are currently being evaluated for measurement of glomerular function.

After injection of gadolinium, the vessels appear high in signal, or white, on T1-weighted sequences. Multiple images can be obtained in a single breath-held acquisition. This technique is useful for lesion characterization in patients who cannot receive iodinated contrast material. As with contrast-enhanced CT, the kidneys initially show symmetric cortical enhancement, which progresses to excretion. A delay in enhancement can be seen with renal artery stenosis.

Magnetic Resonance Urography

There are two techniques for performing magnetic resonance urography (MRU).^{28,29} The first technique is sometimes called static MRU. Because urine contains abundant water, it will demonstrate high signal on a T2-weighted image, so a heavily T2-weighted sequence accentuates the static fluid in the collecting system and ureters, which stands out against the darker background soft tissues. Static MRU can be performed rapidly, which is a benefit in imaging of children. A disadvantage is that any fluid in the abdomen or pelvis, such as fluid collections or fluid in small bowel, will demonstrate similar bright signal that

Figure 5.29 Normal magnetic resonance images through the kidneys. **A**, T1-weighted image. Note the distinct corticomedullary differentiation. **B**, Fast spin echo image. The urine within the collecting tubules causes the high signal within the renal pelvis on this sequence. **C**, Coronal T1-weighted, fat-suppressed image after administration of contrast material. **D**, Axial T1-weighted, fat-suppressed image after administration of contrast material.

can obscure superimposed structures. Also, the collecting system and ureters need to be distended for good images to be obtained.

The second technique, often referred to as excretory MRU, is similar to CTU. Intravenous administration of gadolinium is followed by T1-weighted imaging. This technique allows some assessment of renal function because the contrast material is filtered by the kidney and excreted into the urine (see Fig. 58.12). The opacified collecting system and ureters are well seen, and a diuretic can be administered to further dilate the renal pelvis and ureters if necessary. A limitation of MRU is in the detection of calculi because calcification is poorly visualized by MRI.

CTU and MRU are comparable examinations in identifying the cause and anatomic location of urinary obstruction, and the choice of modality is a matter of local preference. CTU is the better choice in the evaluation of urinary tract calculi. In patients with renal impairment because of obstruction, MRU is superior to CTU in identifying noncalculous causes of obstruction, whereas CTU is superior in identifying calculous causes of obstruction.^{30,31} CTU is also more widely available, faster, and less expensive than MRU. MRU is better suited in patients with allergy to iodinated contrast agents and sometimes in children

when radiation is an issue. MRU is also useful in depicting the anatomy in patients with urinary diversion to bowel conduits.

Magnetic Resonance Angiography

MRA can be performed with or without the intravenous administration of contrast material, although contrast provides better images. The aorta and branch vessels are beautifully demonstrated (Fig. 5.30). By adjustment of timing and type of sequences, the abdominal venous structures can be visualized (Fig. 5.31). MRA is performed to evaluate the renal arteries for stenosis and is less invasive than catheter angiography (Fig. 5.32; see also Fig. 64.18). Technical advances, including faster sequences, now give sensitivity of 97% and specificity of 93% compared with digital subtraction angiography for contrast-enhanced MRA in the detection of renal artery stenosis.³² MRA without gadolinium has a lower sensitivity (53% to 100%) and specificity (65% to 97%) for detection of renal artery stenosis.³³ MRA has limited power to assess accessory renal arteries and therefore is not an ideal study to evaluate fibromuscular dysplasia. It has become the primary screening modality in patients with hypertension,

Figure 5.30 Magnetic resonance angiography. Coronal three-dimensional image after the administration of contrast material showing normal renal arteries.

Figure 5.31 Magnetic resonance venography.

Figure 5.32 Magnetic resonance angiography. Coronal three-dimensional image showing fibromuscular dysplasia of the proximal right renal artery.

declining renal function, or allergy to iodinated contrast agents.³⁴ Where MRA is unavailable, Doppler ultrasound can be used.

Disadvantages of Magnetic Resonance Imaging

MRI, like CT, has some disadvantages. The table and gantry are confining, so claustrophobic patients may be unable to cooperate. Patients with some types of internal metallic hardware, such as pacemakers or cerebral aneurysm clips, cannot undergo MRI. Determination of in-stent stenosis is impossible as metallic artifact from renal artery stents completely obscures the lumen. Even with the new, fast imaging techniques, patients need to be able to cooperate with breath-holding instructions to minimize motion-related artifacts. Furthermore, MRI with gadolinium is contraindicated in patients with GFR below 30 ml/min per 1.73 m² because of the risk of nephrogenic systemic fibrosis (see [Magnetic Resonance Contrast Agents](#)).

MRI can be used in intensive care unit and critically ill patients only if they are stable enough to be transported to the MRI suite and have no implanted metallic devices. Ventilated patients can undergo MRI; however, specific MRI-compatible, nonferromagnetic ventilators and other life support devices must be used. Because of the confined nature of the MRI gantry, visualization and monitoring of the patient during the scan are compromised.

Incidental Findings on CT or MRI

With the growth of cross-sectional imaging, incidental renal lesions are being found with increasing frequency. Nearly 70% of renal cell carcinomas are discovered incidentally on imaging studies performed for other reasons. There is an age-dependent incidence of renal cysts from about 5% in patients younger than 30 years to nearly one third of patients older than 60 years.³⁵ The

differentiation of solid and cystic lesions is the first mandate because as many as two thirds of solid lesions turn out to be malignant.³⁶ MRI is ideally suited for lesion evaluation and is often better than ultrasound, particularly in the case of complex cystic lesions. Parameters being characterized include solid versus cystic, overall lesion complexity, lesion enhancement, involvement of renal vasculature and collecting system, and extension into perirenal tissues and organs. Diffusion-weighted MRI sequences are now also being studied as a means of further differentiating benign and malignant solid lesions.

Measurement of Glomerular Filtration Rate with CT and MRI

Renal blood flow and split renal function can be evaluated by CT and MRI.³⁷⁻³⁹ The attenuation of the accumulated contrast material within the kidney is directly proportional to the GFR. Taking into account the renal volume, the function of each kidney can be determined. Both modalities yield similar information; however, MRI is used more in pediatric patients and in those with allergy to contrast agents. This technique has not yet gained widespread acceptance, and renal scintigraphy remains the standard method for determination of renal function (discussed later).

ANGIOGRAPHY

Angiography is now most often performed for therapeutic intervention, such as embolotherapy or angioplasty and stenting, preceded by diagnostic angiography to evaluate the renal arteries for possible stenosis (Fig. 5.33). With improved resolution and scanning techniques, CTA and MRA have replaced conventional angiography, even for detection of accessory renal arteries, which are often small and bilateral but not infrequently a cause of hypertension. However, angiography remains the gold standard test for the diagnosis of renal artery stenosis and fibromuscular dysplasia. There also remains a role for diagnostic angiography in the evaluation of medium- and large-vessel vasculitis and detection of renal infarction.

The conventional angiogram is performed through arterial puncture followed by catheter placement in the aorta. An abdominal aortogram is obtained to identify the renal arteries. Selective renal artery catheterization can be performed as necessary. Contrast material is administered intra-arterially, and the images are obtained with conventional film or more commonly with digital subtraction angiography. Conventional angiography images are superior but require higher doses of contrast material and more radiation exposure. Digital subtraction angiography uses computer reconstruction and manipulation to generate the images, with the advantage that previously administered and excreted contrast material and bones can be digitally removed to better visualize the renal vasculature. As well as with the risk of contrast-induced nephropathy, angiography is associated with a risk of cholesterol embolization (see Chapter 64). Whereas pathology evidence of cholesterol embolization is frequent, clinically significant symptoms are very uncommon (1% to 2%).⁴⁰

RENAL VENOGRAPHY

Previously, catheter venography was used for evaluation of renal vein thrombosis, for evaluation of gonadal vein thrombosis, and for renal vein sampling to measure renin, but it has largely been

Figure 5.33 Left renal artery stenosis and angioplasty. **A**, Aortogram demonstrating a tight left renal artery stenosis (arrow). **B**, Postangioplasty image with marked improvement of the stenosis (arrow). (Courtesy Dr. Harold Mitty.)

replaced with Doppler ultrasound, followed by contrast-enhanced CT or MRI (see Fig. 5.31).

NUCLEAR MEDICINE

Nuclear scintigraphy evaluates function as well as the anatomy seen with other diagnostic imaging modalities. Radiotracers are designed to accumulate in tissues or organs on the basis of underlying functions unique to that organ. The gamma camera captures the photons from a radiotracer within the patient and generates an image. Single-photon emission computed tomography (SPECT) is a specialized type of imaging whereby the emitted photons are measured at multiple angles, similar to CT, and multiplanar or even three-dimensional images can be created. Three categories of radiotracers that differ in their mode of renal clearance are used in renal imaging: glomerular filtration, tubular secretion, and tubular retention agents (Fig. 5.34).

Choice of Radionuclide in Renal Imaging	
Glomerular filtration rate	^{99m}Tc -DTPA
Glomerular filtration rate with renal impairment	^{99m}Tc -MAG3, ^{131}I -OIH
Effective renal plasma flow	^{99m}Tc -MAG3, ^{131}I -OIH
Renal scarring	^{99m}Tc -DMSA, ^{99m}Tc -GH
Renal pseudotumor	^{99m}Tc -DMSA
Upper renal tract obstruction	^{99m}Tc -DTPA
Upper renal tract obstruction with renal impairment	^{99m}Tc -MAG3

Figure 5.34 Choice of radionuclide in renal imaging.

Scintigraphy remains superior to the other imaging modalities in the evaluation of renal flow and function. It is the study of choice in the evaluation of renal transplants and for the evaluation of functional obstruction, especially when ultrasound evidence is equivocal.

It also provides an accurate assessment of renal function, which assists, for example, in estimating the reduction in renal function to be expected after nephron-sparing surgery. Although CT, MRI, and contrast-enhanced ultrasound are being assessed for the evaluation of renal function, scintigraphy remains the preferred modality. Both CTA and MRA have replaced nuclear scintigraphy in the evaluation of renal artery stenosis and in evaluation of benign renal masses, such as a column of Bertin. Nuclear medicine is still used to assess the functional significance of renal artery stenosis independent of anatomy.

Glomerular Filtration Agents

Glomerular filtration agents are cleared by the glomerulus and can be used to measure GFR. Technetium ^{99m}Tc -labeled diethylenetriaminepentaacetic acid (^{99m}Tc -DTPA) is the most common glomerular agent used for imaging and can also be used for GFR calculation. In patients with poor renal function, renal imaging with tubular secretion agents such as mercaptoacetyltri-glycine (^{99m}Tc -labeled MAG3) is superior to DTPA.^{41,42}

Tubular Secretion Agents

^{99m}Tc -MAG3 is handled primarily by tubular secretion and can be used to estimate effective renal plasma flow. The clearance rate for ^{99m}Tc -MAG3 is 340 ml/min.⁴³

Tubular Retention Agents

Tubular retention agents include ^{99m}Tc -labeled dimercaptosuccinate (DMSA) and less commonly ^{99m}Tc -labeled glucoheptonate (GH). These agents provide excellent cortical imaging and can be used in suspected renal scarring or infarction, in pyelonephritis, and for clarification of renal pseudotumors. These agents bind with high affinity to the sulfhydryl groups of the proximal tubules.

Renogram

A renogram is generated by scintigraphy and provides information about blood flow, renal uptake, and excretion. Time-activity

Figure 5.35 Normal ^{99m}Tc -labeled DTPA study: time-activity curves. **A**, Early (0-1 minute), showing renal blood flow. **B**, Later (0-30 minutes), showing renal uptake and excretion of tracer. (Courtesy Dr. Chun Kim.)

graphs are produced that plot blood flow of the radiotracer into each kidney relative to the aorta. Peak cortical enhancement and pelvicalyceal clearance of the tracer are also plotted. DTPA or MAG3 can be used to generate the renogram. The relative radiotracer uptake can be measured and can provide split or differential information about renal function (Fig. 5.35).

The blood pool or flow images are obtained after bolus injection of the radiotracers. Images are obtained with the gamma camera every few seconds for the first minute. The second component of the renogram evaluates renal function by measuring radiotracer uptake and excretion by the kidney. In normal patients, the peak renal cortical concentration occurs between 3 and 5 minutes after injection of tracer. Delayed transit of the isotope secondary to renal dysfunction (e.g., acute tubular necrosis or rejection) or obstructive uropathy will alter the curve of the renogram.

In cases of suspected obstructive uropathy, a diuresis renogram can be obtained. A loop diuretic is injected intravenously when radiotracer activity is present in the renal pelvis; a computer-generated washout curve is obtained. In patients with true obstruction, activity will remain in the renal pelvis, whereas it will quickly wash out in patients without an obstruction (Fig. 5.36; see also Figs. 50.21, 50.22, and 58.14).

Figure 5.36 Diuresis renogram showing obstructed right kidney. Isotope continues to accumulate in the right kidney despite intravenous furosemide (given at ↓). Isotope excretion in the left kidney is normal.

Figure 5.37 Renal infarct. ^{99m}Tc -DMSA scan in a newborn with a right lower pole infarct secondary to an embolus from an umbilical catheter. (Courtesy Dr. Chun Kim.)

Cortical Imaging

Renal cortical imaging is performed with tubular retention agents, usually ^{99m}Tc -DMSA. Information about renal size, location, and contour can be obtained (Fig. 5.37). The study is most commonly used for evaluation of renal scarring, particularly in children with reflux or chronic infections (see Chapter 61). It was formerly used for clarification of renal pseudotumors, such as a suspected column of Bertin, but this is now done with CT and MRI. Split renal function can also be determined from cortical imaging. Pinhole imaging (with a pinhole collimator, which magnifies the kidney to provide more anatomic detail than with planar imaging) and, more recently, SPECT imaging have been found useful for detection of cortical defects caused by inflammation or scarring. Cortical imaging may be better than ultrasound in the evaluation of the young patient with urinary tract infection.⁴⁴ Any infection, scar, or space-occupying lesion (tumor or cyst) will give a cortical defect, and correlation of the cortical defect site with other cross-sectional imaging should be performed to differentiate these entities.

Vesicoureteral Reflux

In children with suspected vesicoureteral reflux, a standard cystogram is obtained. If reflux is shown, follow-up is subsequently

performed with radioisotope cystography, which exposes the child to a lower radiation dose and can be used to quantitate the bladder capacity when reflux occurs. The study is performed after instillation of technetium pertechnetate through a catheter into the bladder. Images are obtained during voiding.

Renal Transplant

Renal transplants are easily evaluated with scintigraphy. Because many transplant recipients develop declining renal function, ^{99m}Tc -MAG3 is the first-choice nuclide.

As with the normal kidneys, information about blood flow and function can be determined. Postoperative complications involving the artery, vein, or ureter are also well delineated. Nuclear imaging can help define acute tubular necrosis versus rejection in transplant patients with declining renal function. Ultrasound with Doppler evaluation of resistive index is often a complementary investigation, and choice of imaging modality in part depends on local expertise and preference.

Angiotensin-Converting Enzyme Inhibitor Renography

Angiotensin-converting enzyme (ACE) inhibitor renography was developed to detect renal artery stenosis. It relies on changes in scintigraphic findings that are exaggerated by administration of an ACE inhibitor, usually captopril. The limitation of captopril renography is poor sensitivity with impaired renal function and with bilateral renal artery stenosis. It has been almost completely replaced by CTA or MRA.^{45,46}

POSITRON EMISSION TOMOGRAPHY

PET scanning uses radioactive positron emitters (most commonly ^{18}F -labeled fluorodeoxyglucose [FDG]). The FDG is intravenously injected and distributes in the body according to metabolic activity. Any process, such as tumor or infection, that causes increased metabolic activity will result in an area of increased uptake on the scan. These areas of abnormality need to be differentiated from normally hypermetabolic tissues, such as brain, liver, bone marrow, and to some extent heart and bowel (Fig. 5.38). Because FDG is cleared through the kidneys and excreted in the urine, PET scanning has a limited role in renal imaging, but it is useful in the staging and follow-up of metastatic renal cancer.^{47,48}

MOLECULAR IMAGING

With molecular imaging, radiology is moving from the identification of generic anatomy and nonspecific enhancement patterns to assessment of specific molecular differences in tissues and disease processes. Nuclear imaging presently is molecular based but still nonspecific (e.g., FDG-PET, renal DTPA). The newer focus of molecular imaging studies dynamic processes like metabolic activity, cell proliferation, apoptosis, receptor status, and antigen modulation. Typically, this involves imaging of biochemical and physiologic processes. Techniques are being developed with use of optical scanning, MRI, and ultrasound as well as with radionuclides.

Applications are established in clinical practice, particularly in oncology (e.g., CD20 imaging in lymphoma), and work is under way for renal-specific molecular imaging. For example, MR renal cell imaging may soon be available to help differentiate acute

tubular necrosis from renal rejection and renal cell cancer from benign tumors.

RADIOLOGIC CONTRAST AGENTS

X-ray Contrast Agents

Contrast agents continue to have a role in many imaging techniques. A tri-iodinated benzene ring forms the chemical basis for CT intravascular contrast agents. Conventional contrast agents have high osmolality, about five times greater than plasma osmolality. They give excellent renal opacification, but this contributes to their toxicity. Modifications to the benzene ring have led to newer contrast agents, including low-osmolar and more recently iso-osmolar nonionic agents, which are less nephrotoxic.

Intravascular iodinated contrast material rapidly passes through the capillary pores into the interstitial, extracellular space and into the renal tubules through glomerular filtration.⁴⁹ In patients with normal renal function, the kidneys eliminate almost all of the contrast agent. Extrarenal routes of excretion include the liver and bowel wall and account for less than 1% of elimination but can increase when renal function is compromised. The half-time for elimination in patients with normal renal function is 1 to 2 hours, compared with 2 to 4 hours in dialysis patients.⁵⁰

The overall incidence of contrast reactions for iodinated agents is 3.1% to 4.7%.⁵¹⁻⁵³ Twenty percent of patients who have a contrast reaction will experience a reaction on re-exposure that may be similar or worse. Contrast reactions can be anaphylactoid or chemotoxic reactions. The anaphylactoid reactions mimic an allergic response, whereas the chemotoxic reactions are believed to be mediated by direct toxic effects of the contrast material.

The exact mechanism of contrast reaction is not known but is likely to be multifactorial. Formation of antigen-antibody complexes, complement activation, protein binding, and histamine release have all been cited as possible mechanisms.

Reactions may be minor, intermediate, or severe. Minor reactions include heat sensation, nausea, and mild urticaria. Intermediate reactions include vasovagal reaction, bronchospasm, and generalized urticaria. Severe reactions include profound hypotension, pulmonary edema, and cardiac arrest. The use of low-osmolar or iso-osmolar contrast agents reduces the incidence of minor and intermediate contrast reactions. The incidence of death related to high-osmolar contrast agents is reported to be 1 in 40,000. Immediate treatment of reactions should be directed toward the symptoms. In patients with a history of contrast allergy, pretreatment on re-exposure is usually recommended. Various protocols are used but typically include antihistamines and corticosteroids.

Contrast-Induced Nephropathy

Renal failure associated with the administration of contrast material has been reported as the third most common cause of in-hospital renal failure.⁵³ Patients with normal renal function rarely develop contrast-induced renal failure. In patients with GFR below 60 ml/min, iodinated contrast agents should be used with caution because the risk for contrast-induced nephropathy is increased. Nephrotoxicity ranges in severity from a nonoliguric transient fall in GFR to severe renal failure requiring dialysis. The combination of preexisting renal impairment and diabetes is the major risk factor. Other risk factors are cardiovascular disease, the use of diuretics, advanced age (>75 years), multiple myeloma in dehydrated patients, hypertension, uricosuria, and high dose of contrast material. Both ionic and nonionic contrast media can induce nephrotoxicity, although nonionic contrast material is significantly less nephrotoxic. In end-stage renal disease, fluid overload may follow the use of contrast material because of thirst provoked by the osmotic load.

The two major theories for the pathogenesis of contrast-induced nephropathy are renal vasoconstriction, perhaps mediated by alterations in nitric oxide, and direct nephrotoxicity of the contrast agent. Most underlying cellular events occur within the first 60 minutes after administration of the contrast agent, with the greatest risk in the first 10 minutes.

There is some evidence that people with diabetes and heart failure have altered nitric oxide metabolism, which may account for their increased risk for contrast-induced nephrotoxicity. Tubular injury produces oxygen free radicals, possibly as a result of the vasoconstriction. In animal studies, reduction in antioxidant enzymes associated with hypovolemia contributes to the injury.⁵⁴ Hydration is the mainstay of prevention, and hydration with intravenous sodium bicarbonate solution rather than with sodium chloride has been shown to give added benefit.⁵⁵ Acetylcysteine, a thiol-containing antioxidant given in conjunction with hydration, has not proved consistently to be protective.⁵⁶ In most patients, the renal failure is transient, and the patients recover without incident.

An important differential diagnosis for contrast-induced nephropathy in patients with vascular disease undergoing catheter angiography is cholesterol embolization (see Chapter 64).

In patients with GFR below 60 ml/min, low-osmolar or iso-osmolar contrast agents should be used and the doses reduced. Repetitive, closely performed contrast studies should be avoided. In high-risk patients, alternative imaging studies, ultrasound,

MRI, or noncontrast CT should always be considered. The prevention and management of contrast nephrotoxicity are discussed further in Chapter 64.

Magnetic Resonance Contrast Agents

There are two classes of MRI contrast agents: diffusion agents and nondiffusion agents. Diffusion agents, with appropriate timing of imaging sequences, can give delineation of vessels as well as of parenchymal tissues. Nondiffusion agents remain in the blood stream and are primarily useful for MRA. All of the contrast agents are based on the paramagnetic properties of gadolinium. Gadolinium itself is highly toxic and is given only when it is tightly chelated (e.g., Gd-DOTA, Gd-DTPA).

Minor reactions, such as headache and nausea, occur in 3% to 5% of patients; but severe life-threatening reactions and nephrotoxic reactions are rare. In patients with renal impairment, a rare severe reaction, nephrogenic systemic fibrosis, has been described (discussed further in Chapter 84), and therefore the use of gadolinium agents is generally contraindicated in patients with impaired renal function. In the United States, gadolinium is typically avoided at GFR below 30 ml/min.

Renal Biopsy

Peter S. Topham, Yipu Chen

DEFINITION

Percutaneous renal biopsy was first described in the early 1950s by Iversen and Brun¹ and Alwall.² These early biopsies were performed with the patients in the sitting position by use of a suction needle and intravenous urography for guidance. An adequate tissue diagnosis was achieved in less than 40% of these early cases. In 1954, Kark and Muehrcke³ described a modified technique in which the Franklin-modified Vim-Silverman needle was used, the patient lay in a prone position, and an exploring needle was used to localize the kidney before insertion of the biopsy needle. These modifications yielded a tissue diagnosis in 96% of cases, and no major complications were reported. Since then, the basic renal biopsy procedure has remained largely unchanged, although the use of real-time ultrasound and refinement of biopsy needle design have offered significant improvements. Renal biopsy is now able to provide a tissue diagnosis in more than 95% of cases with a life-threatening complication rate of less than 0.1%.

INDICATIONS FOR RENAL BIOPSY

The indications for renal biopsy are listed in Figure 6.1. Ideally, analysis of a renal biopsy sample should identify a specific diagnosis, reflect the level of disease activity, and provide information to allow informed decisions about treatment to be made. Although the renal biopsy is not always able to fulfill these criteria, it remains a valuable clinical tool and is of particular benefit in the following clinical situations.

Nephrotic Syndrome

Routine clinical and serologic examination of patients with nephrotic syndrome usually allows the clinician to determine whether a systemic disorder is present. In adults and adolescents beyond puberty without systemic disease, there is no reliable way to predict the glomerular pathologic process with confidence by noninvasive criteria alone; therefore, a renal biopsy should be performed. In children aged between 1 year and puberty, a presumptive diagnosis of minimal change disease can be made. Renal biopsy is reserved for nephrotic children with atypical features (microscopic hematuria, reduced serum complement levels, renal impairment, failure to respond to corticosteroids).

Acute Kidney Injury

In most patients with acute kidney injury (AKI) or AKI on a background of chronic kidney disease (CKD), the cause can be determined without a renal biopsy. Obstruction, reduced renal perfusion, and acute tubular necrosis can usually be identified

from other lines of investigation. In a minority of patients, however, a confident diagnosis cannot be made. In these circumstances, a renal biopsy should be performed as a matter of urgency so that appropriate treatment can be started before irreversible renal injury develops. This is particularly the case if AKI is accompanied by an active urine sediment or if drug-induced or infection-induced acute interstitial nephritis is suspected.

Systemic Disease Associated with Renal Dysfunction

Patients with diabetes mellitus and renal dysfunction do not usually require a biopsy if the clinical setting is compatible with diabetic nephropathy (isolated proteinuria, diabetes of long duration, evidence of other microvascular complications). However, if the presentation is atypical (proteinuria associated with glomerular hematuria [acanthocytes], absence of retinopathy or neuropathy [in patients with type 1 diabetes], onset of proteinuria less than 5 years from documented onset of diabetes, uncharacteristic change in renal function or renal disease of acute onset, the presence of immunologic abnormalities), a renal biopsy should be performed.

Serologic testing for antineutrophil cytoplasmic antibodies (ANCA) and for anti-glomerular basement membrane antibodies has made it possible to make a confident diagnosis of renal small-vessel vasculitis or Goodpasture's disease without invasive measures in most patients. Nonetheless, a renal biopsy should still be performed to confirm the diagnosis and to clarify the extent of active inflammation versus chronic fibrosis and hence the potential for recovery. This information may be important in helping to decide whether to initiate or to continue immunosuppressive therapy, particularly in patients who may tolerate immunosuppression poorly.

Lupus nephritis can usually be diagnosed by noninvasive criteria (autoantibodies, urine protein excretion, renal function, and urine sediment abnormalities). Some experts argue that this information can be used to gauge the severity of renal involvement and to inform decisions about initial immunosuppressive treatment. However, a renal biopsy will clarify the underlying pathologic lesion, the level of acute activity, and the extent of chronic fibrosis, thereby providing robust guidance for evidence-based therapy.

The diagnosis of virus infection-related nephropathy, for example, hepatitis B virus-associated membranous nephropathy, is suggested by the presence of the expected glomerular lesion in association with evidence of active viral infection. However, the identification of virus-specific protein or DNA or RNA in the renal biopsy tissue by immunopathologic and molecular pathologic techniques (e.g., *in situ* hybridization) can ensure the diagnosis.

Indications for Renal Biopsy	
Nephrotic Syndrome	Routinely indicated in adults; in prepubertal children, only if clinical features atypical of minimal change disease
Acute Kidney Injury	Indicated if obstruction, reduced renal perfusion, and acute tubular necrosis have been ruled out
Systemic Disease with Renal Dysfunction	Indicated in patients with small-vessel vasculitis, anti-glomerular basement-membrane disease, and systemic lupus; those with diabetes only if atypical features present
Non-nephrotic Proteinuria	May be indicated if proteinuria >1g/24h
Isolated Microscopic Hematuria	Indicated only in unusual circumstances
Unexplained Chronic Kidney Disease	May be diagnostic, (e.g., identify IgA nephropathy even in “end-stage kidney”)
Familial Renal Disease	Biopsy of one affected member may give diagnosis and minimize further investigation of family members
Renal Transplant Dysfunction	Indicated if ureteral obstruction, urinary sepsis, renal artery stenosis, and toxic calcineurin inhibitor levels are not present

Figure 6.1 Indications for renal biopsy. See text for further discussion.

Other systemic diseases, such as amyloidosis, sarcoidosis, and myeloma, can be diagnosed with a renal biopsy. However, because these diagnoses can often be made by other investigative approaches, a renal biopsy is indicated only if the diagnosis remains uncertain or if knowledge of renal involvement would change management.

Renal Transplant Dysfunction

Renal allograft dysfunction in the absence of ureteral obstruction, urinary sepsis, renal artery stenosis, or toxic levels of calcineurin inhibitors requires a renal biopsy to determine the cause. In the early post-transplantation period, this is most useful in differentiating acute rejection from acute tubular necrosis and the increasingly prevalent BK virus nephropathy. Later, renal biopsy can differentiate late acute rejection from chronic allograft nephropathy, recurrent or *de novo* glomerulonephritis, and calcineurin inhibitor toxicity. The accessible location of the renal transplant in the iliac fossa facilitates biopsy of the allograft and allows repeated biopsies when indicated. This has encouraged many units to adopt a policy of protocol (surveillance) biopsies to detect subclinical acute rejection and renal scarring and to guide the choice of immunosuppressive therapy (see Chapter 100).

Non-nephrotic Proteinuria

The value of renal biopsy in patients with non-nephrotic proteinuria is debatable. All conditions that result in nephrotic syndrome can cause non-nephrotic proteinuria with the exception

of minimal change disease. However, the benefit of specific treatment with corticosteroids and other immunosuppressive agents in this clinical setting probably does not justify the risk of significant drug-related side effects. In patients with proteinuria of more than 1 g/day, generic treatment with strict blood pressure control and angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) alone or in combination reduces proteinuria and reduces the risk for development of progressive renal dysfunction. Nonetheless, although the renal biopsy may not lead to an immediate change in management, it can be justified in these circumstances because it will provide prognostic information, may identify a disease for which a different therapeutic approach is indicated, and may provide clinically important information about the future risk of disease recurrence after renal transplantation.

Isolated Microscopic Hematuria

Patients with microscopic hematuria should initially be evaluated to identify structural lesions such as renal stones or renal and urothelial malignant neoplasms if they are older than 40 years. The absence of a structural lesion suggests that the hematuria may have a glomerular source. Biopsy studies have identified glomerular lesions in up to 75% of biopsies.⁴ In all series, IgA nephropathy has been the most common lesion, followed by thin basement membrane nephropathy. In the absence of nephrotic proteinuria, renal impairment, or hypertension, the prognosis for these conditions is excellent, and because specific therapies are not available, renal biopsy in this setting is not necessary. Biopsy should be performed only if the result would provide reassurance to the patient, avoid repeated urologic investigations, or provide specific information (e.g., in the evaluation of potential living kidney donors, in familial hematuria, for life insurance and employment purposes).

Unexplained Chronic Kidney Disease

Renal biopsy can be informative in the patient with unexplained CKD with normal-sized kidneys because in contrast to AKI, it is often difficult to determine the underlying cause on the basis of clinical criteria alone. Studies have shown that in this setting, the biopsy will demonstrate disease that was not predicted in almost half of cases.⁵ However, if both kidneys are small (<9 cm on ultrasound), the risks of the biopsy are increased, and the diagnostic information available from the biopsy may be limited by extensive glomerulosclerosis and tubulointerstitial fibrosis. In this setting, however, immunofluorescence studies may still be informative. For example, glomerular IgA deposition may be identified despite advanced structural damage.

Familial Renal Disease

A renal biopsy can be helpful in the investigation of patients with a family history of renal disease; and a biopsy performed on one affected family member may secure the diagnosis for the whole family and avoid the need for repeated investigation. Conversely, a renal biopsy may unexpectedly identify disease that has an inherited basis, thereby stimulating evaluation of other family members.

The Role of Repeated Renal Biopsy

In some circumstances, a repeated biopsy may be indicated. For example, the pathologic changes in lupus nephritis may evolve,

and treatment adjustment may be necessary; minimal change disease that is corticosteroid resistant or dependent or frequently relapsing may actually represent a missed diagnosis of focal segmental glomerulosclerosis (FSGS), which may be detected on a repeated biopsy; and some nephrologists would argue that a repeated biopsy in patients who have had aggressive immunosuppressive treatment of crescentic glomerulonephritis can help in determining the most appropriate next line of therapy.

VALUE OF THE RENAL BIOPSY

Biopsy Adequacy

In the assessment of a renal biopsy, the number of glomeruli in the sample is the major determinant of whether the biopsy will be diagnostically informative.

For a focal disease such as FSGS, the diagnosis can potentially be made on a biopsy specimen containing a single glomerulus that contains a typical sclerosing lesion. However, the probability that FSGS is not present in a patient with nephrotic syndrome and minimal changes on the biopsy specimen is dependent on the actual proportion of abnormal glomeruli in the kidney and the number of glomeruli obtained in the biopsy specimen. For example, if 20% of glomeruli in the kidney have sclerosing lesions and five glomeruli are sampled, there is a 35% chance that all the glomeruli in the biopsy specimen will be normal and that the biopsy will miss the diagnosis. By contrast, in the same kidney, if 10 or 20 glomeruli are sampled, the chance of obtaining all normal glomeruli is reduced to 10% and less than 1%, respectively, and the biopsy is more discriminating. This argument assumes that any segmental lesions present in the biopsy specimen are actually identified; this requires the biopsy specimen to be sectioned at multiple levels.

Unless all glomeruli are affected equally, the probability that the observed involvement in the biopsy specimen accurately reflects true involvement in the kidney depends not only on the number of glomeruli sampled but also on the proportion of affected glomeruli. For example, in a biopsy specimen containing 10 glomeruli of which three are abnormal (30%), there is a 95% probability that the actual glomerular involvement is between 7% and 65%. In the same kidney, if the biopsy specimen contained 30 glomeruli with 30% being abnormal, the 95% confidence intervals are narrowed to 15% and 50%.

Therefore, the interpretation of the biopsy needs to take into account the number of glomeruli obtained. A typical biopsy sample will contain 10 to 15 glomeruli and will be diagnostically useful. Nonetheless, it must be appreciated that because of the sampling issue, a biopsy sample of this size will occasionally be unable to diagnose focal diseases and at best will provide imprecise guidance on the extent of glomerular involvement.

An adequate biopsy should also provide samples for immunohistology and electron microscopy. Immunohistology is provided by either immunofluorescence on frozen material or immunoperoxidase on fixed tissue, according to local protocols and expertise. It is helpful for the biopsy cores to be viewed under an operating microscope immediately after being taken to ensure that they contain cortex and that when the cores are divided, the immunohistology and electron microscopy samples both contain glomeruli.

If insufficient material for a complete pathologic evaluation is obtained, there should be a discussion with the pathologist about how best to proceed before the tissue is placed in fixative so that the material can be processed in a way that will provide maximum

information for the specific clinical situation. For example, if the patient has heavy proteinuria, most information will be gained from electron microscopy because it is able to demonstrate podocyte foot process effacement, focal sclerosis, electron-dense deposits of immune complexes, and the organized deposits of amyloid.

If a sample is supplied for immunofluorescence microscopy but contains no glomeruli, it may be possible to reprocess the paraffin-embedded sample to identify immune deposits by either immunoperoxidase or immunofluorescence techniques.

Is Renal Biopsy a Necessary Investigation?

The role of the renal biopsy has been much debated. Early studies suggested that renal biopsy provided diagnostic clarity in the majority of cases but that this information did not alter management, with the exception of those with heavy proteinuria or systemic disease. More recent prospective studies have suggested that the renal biopsy identifies a diagnosis different from that predicted on clinical grounds in 50% to 60% of patients and leads to a treatment change in 20% to 50% of cases.⁶ This is particularly apparent in patients with heavy proteinuria or AKI, in whom the biopsy findings alter management in more than 80% of cases.⁷

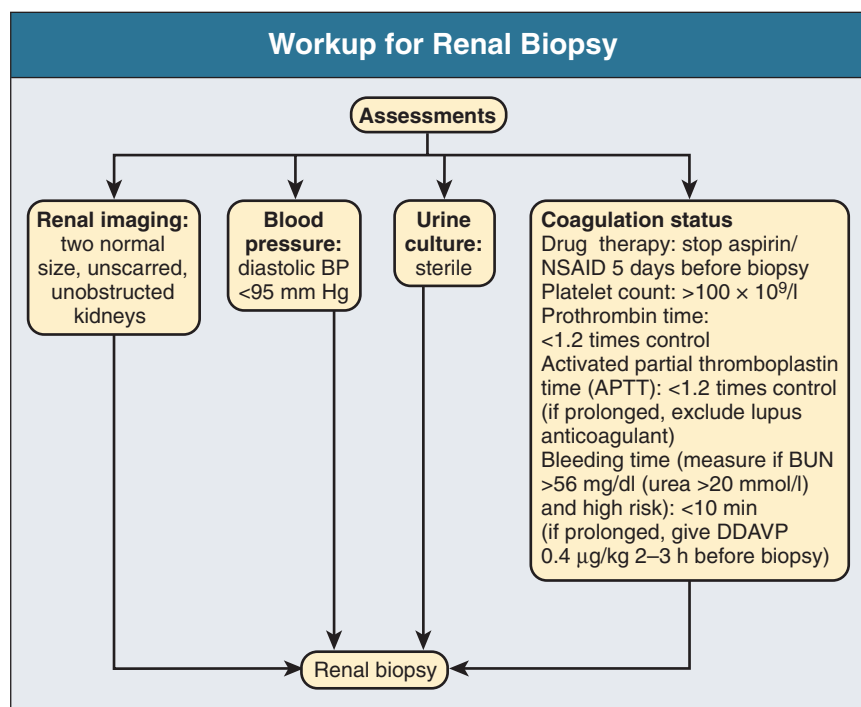

PREBIOPSY EVALUATION

This evaluation identifies issues that may compromise the safety and success of the procedure (Fig. 6.2). It will determine whether the patient has two normal-sized unobstructed kidneys, sterile urine, controlled blood pressure, and no bleeding diathesis. A thorough history should be taken to identify evidence of a bleeding diathesis, such as previous prolonged surgical bleeding, spontaneous bleeding, family history of bleeding, and ingestion of medication that increases bleeding risk (including antiplatelet agents and warfarin).

An ultrasound scan should be performed to assess kidney size and to identify significant anatomic abnormalities, such as solitary kidney, polycystic or simple cystic kidneys, malpositioned kidneys, horseshoe kidneys, small kidneys, or hydronephrosis.

The value of the bleeding time in patients undergoing renal biopsy is controversial. The predictive value of the bleeding time for postrenal biopsy bleeding has never been prospectively tested. Retrospective studies, however, demonstrated a threefold to fivefold increase in bleeding complications after renal biopsy in patients with prolonged bleeding times. Prospective studies of percutaneous liver biopsy patients showed a fivefold increase in bleeding complications in those with uncorrected bleeding times.⁸ A consensus document concluded that the bleeding time is a poor predictor of postsurgical bleeding but that it does correlate with clinical bleeding episodes in uremic patients.⁹

Several approaches to the management of bleeding risk have been adopted: many centers measure the prebiopsy bleeding time and administer 1-desamino-8-D-arginine vasopressin (desmopressin or DDAVP) if the bleeding time is prolonged beyond 10 minutes; another preferred method is to no longer measure the bleeding time, but routinely administer DDAVP to those patients with significant renal impairment (blood urea nitrogen level >56 mg/dl [urea >20 mmol/l] or serum creatinine concentration >3 mg/dl [250 μmol/l]); in other centers, a platelet transfusion is used in preference to DDAVP. Platelet transfusion can also be used to reverse clopidogrel-induced platelet dysfunction when the renal biopsy is urgent.

Figure 6.2 Workup for renal biopsy.

Contraindications to Renal Biopsy	
Kidney Status	Patient Status
Multiple cysts	Uncontrolled bleeding diathesis
Solitary kidney	Uncontrolled blood pressure
Acute pyelonephritis/ perinephric abscess	Uremia
Renal neoplasm	Obesity Uncooperative patient

Figure 6.3 Contraindications to renal biopsy. Most contraindications to renal biopsy are relative rather than absolute; when clinical circumstances necessitate urgent biopsy, they may be overridden, apart from uncontrolled bleeding diathesis.

The use of thromboelastography (TEG) has been described in the renal transplant biopsy setting.¹⁰ TEG provides an overall measure of the coagulation, platelet, and fibrinolytic systems in one assay and therefore may be more predictive of clinical bleeding. In this study, most bleeding episodes were associated with normal clotting test results, but TEG was the only assay that was associated with an increased risk of postbiopsy bleeding. The role of TEG in native kidney renal biopsy requires further evaluation.

Contraindications to Renal Biopsy

The contraindications to percutaneous renal biopsy are listed in Figure 6.3. The major contraindication is a bleeding diathesis. If the disorder cannot be corrected and the biopsy is deemed indispensable, alternative approaches, such as open biopsy, laparoscopic biopsy, or transvenous (usually transjugular) biopsy, can be performed. Inability to comply with instructions

during the biopsy is a further major contraindication to renal biopsy. Sedation or, in extreme cases, general anesthesia may be necessary.

Hypertension (>160/95 mm Hg), hypotension, perinephric abscess, pyelonephritis, hydronephrosis, severe anemia, large renal tumors, and cysts are relative contraindications to renal biopsy. When possible, they should be corrected before the biopsy is undertaken.

The presence of a solitary functioning kidney has been considered a contraindication to percutaneous biopsy, and it has been argued that the risk of biopsy is reduced by direct visualization at open biopsy. However, the postbiopsy nephrectomy rate of 1/2000 to 1/5000 is comparable to the mortality rate associated with the general anesthetic required for an open procedure. Therefore, in the absence of risk factors for bleeding, percutaneous biopsy of a solitary functioning kidney can be justified.

RENAL BIOPSY TECHNIQUE

Percutaneous Renal Biopsy

Native Renal Biopsy

In our center, the kidney biopsy is performed by nephrologists with continuous (real-time) ultrasound guidance and disposable automated biopsy needles. We use 16-gauge needles as a compromise between the greater tissue yield of larger needles and the trend to fewer bleeding complications of smaller needles. For most patients, premedication or sedation is not required. The patient is laid prone, and a pillow is placed under the abdomen at the level of the umbilicus to straighten the lumbar spine and to splint the kidneys. Figure 6.4 shows the anatomic relationships of the left kidney. Ultrasound is used to localize the lower pole of the kidney where the biopsy will be performed (usually the left kidney). An indelible pen mark is used to indicate the point of entry of the biopsy needle. The skin is sterilized with either

Figure 6.4 Computed tomography through the left kidney. The angle of approach of the needle is demonstrated. Note the relative adjacency of the lower pole of the kidney to other structures, particularly the large bowel.

povidone-iodine (Betadine) or chlorhexidine solution. A sterile fenestrated sheet is placed over the area to maintain a sterile field. Local anesthetic (2% lidocaine [lignocaine]) is infiltrated into the skin at the point previously marked. While the anesthetic takes effect, the ultrasound probe is covered in a sterile sheath. Sterile ultrasound jelly is applied to the skin, and under ultrasound guidance, a 10-cm, 21-gauge needle is guided to the renal capsule and further local anesthetic infiltrated into the perirenal tissues and then along the track of the needle on withdrawal. A stab incision is made through the dermis to ease passage of the biopsy needle. This is passed under ultrasound guidance to the kidney capsule (Fig. 6.5). As the needle approaches the capsule, the patient is instructed to take a breath until the kidney is moved to a position such that the lower pole rests just under the biopsy needle and then to stop breathing. The biopsy needle tip is advanced to the renal capsule, and the trigger mechanism is released, firing the needle into the kidney (Fig. 6.6). The needle is immediately withdrawn, the patient is asked to resume breathing, and the contents of the needle are examined (Fig. 6.7). We examine the tissue core under an operating microscope to ensure that renal cortex has been obtained (Fig. 6.8). A second pass of the needle is usually necessary to obtain additional tissue for immunohistology and electron microscopy. If insufficient tissue is obtained, further passes of the needle are made. However, in our experience, if the needle is passed more than four times, a modest increase in the postbiopsy complication rate is observed.

Once sufficient renal tissue has been obtained, the skin incision is dressed and the patient is rolled directly into bed for observation.

No single fixative has been developed that allows good-quality light microscopy, immunofluorescence, and electron microscopy to be performed on the same sample. In our center, therefore, the renal tissue is divided into three samples and placed in

Figure 6.5 Renal biopsy procedure. The biopsy needle is introduced at an angle of approximately 70 degrees to the skin and is guided by continuous ultrasound. The operator is shown wearing a surgical gown. This is not strictly necessary; sterile gloves and maintenance of a sterile field are sufficient.

Figure 6.6 Renal biopsy. Ultrasound scan demonstrating the needle entering the lower pole of the left kidney. The arrows indicate the needle track, which appears as a fuzzy white line.

Figure 6.7 Renal biopsy. A core of renal tissue is demonstrated in the sampling notch of the biopsy needle.

formalin for light microscopy, normal saline for subsequent snap-freezing in liquid nitrogen for immunofluorescence, and glutaraldehyde for electron microscopy.

There are a number of variations of the percutaneous renal biopsy technique. Whereas the majority of biopsies are guided by ultrasound, some operators choose to use it only to localize the kidney and to determine the depth and angle of approach of the needle, then performing the biopsy without further ultrasound guidance. The success and complication rates appear to be no different from those seen with continuous ultrasound guidance. For technically challenging biopsies, computed tomography can be used to guide the biopsy needle.

For obese patients and patients with respiratory conditions who find the prone position difficult, the supine anterolateral approach has recently been described.¹¹ Patients lie supine with the flank on the side to be sampled elevated by 30 degrees with towels under the shoulder and gluteus. The biopsy needle is inserted through Petit's triangle (bounded by latissimus dorsi muscle, 12th rib, and iliac crest). This technique provides good access to the lower pole of the kidney, is better tolerated than the prone position by such patients, and has a diagnostic yield and safety profile comparable to the standard technique.

Renal Transplant Biopsy

Biopsy of the transplant kidney is facilitated by the proximity of the kidney to the anterior abdominal wall and the lack of movement on respiration. It is performed under real-time ultrasound

guidance with use of an automated biopsy needle. In most cases, the renal transplant biopsy is performed to identify the cause of acute allograft dysfunction. In these circumstances, the aim is to identify acute rejection, and therefore the diagnosis can be made on a formalin-fixed sample alone for light microscopy. If vascular rejection is suspected, a snap-frozen sample for C4d immunostaining should also be obtained. If recurrent or *de novo* glomerulonephritis is suspected in patients with chronic allograft dysfunction, additional samples for electron microscopy and immunohistology should be collected.

Postbiopsy Monitoring

After the biopsy, the patient is placed supine and subjected to strict bed rest for 6 to 8 hours. The blood pressure is monitored frequently, the urine is examined for macroscopic hematuria, and the skin puncture site is examined for excessive bleeding. If there is no evidence of bleeding after 6 hours following biopsy, the patient is sat up in bed and subsequently allowed to mobilize. If macroscopic hematuria develops, bed rest is continued until the bleeding settles.

Conventionally, patients have been kept in the hospital for 24 hours after a biopsy to be observed for complications. However, outpatient (day-case) renal biopsy with same-day discharge after 6 to 8 hours of observation has become increasingly popular for both native and renal transplant biopsies. This has been largely driven by the financial and resource implications of overnight hospital admission and has been justified by the perception that the significant complications of renal biopsy will become apparent during this shortened period of observation. This view has been challenged by a study of 750 native renal biopsies, which showed that only 67% of major complications (i.e., those that either required blood transfusion or an invasive procedure or resulted in urinary tract obstruction, septicemia, or death) were apparent by 8 hours after biopsy.¹² The authors concluded that the widespread application of an early discharge policy after renal biopsy is not in the patient's best interest and that a 24-hour period of observation is preferable.

In our center, approximately half of our renal biopsies are performed on an outpatient basis. The patient population is selected to avoid those with the highest risk of complications, for example, impaired renal function (creatinine concentration >3 mg/dl [250 μ mol/l]), small kidneys, and uncontrolled hypertension. In addition, we require that the patient not be alone at home for at least one night after the biopsy. This selection policy has proved to be safe. Of the last 429 outpatient biopsies performed in our unit, 6% developed a self-limited postbiopsy complication within 6 hours that required a short hospital admission. Five patients returned after same-day discharge with biopsy-related complications, one with macroscopic hematuria 24 hours after the biopsy and four with loin pain between 3 and 5 days after biopsy. All patients recovered with conservative management. In our opinion, outpatient renal biopsy is acceptably safe when a low-risk patient group is selected.

A study has examined whether ultrasound 1 hour after biopsy is able to predict bleeding complications.¹³ The absence of hematoma was predictive of an uncomplicated course, but the identification of hematoma was not reliably predictive of a significant biopsy complication (identification of hematoma at 1 hour had a 95% negative predictive value and 43% positive predictive value). The role of this practice in the wider clinical setting remains to be determined given the additional expense of the routine postbiopsy ultrasound scan.

Alternatives to the Percutaneous Approach

When the percutaneous approach is contraindicated, other approaches to renal biopsy have been described. The choice of technique depends on the safety, morbidity, recovery period, and adequacy of the technique, but probably above all on the local expertise that is available.

Transvenous (Transjugular or Transfemoral) Renal Biopsy

Transvenous sampling of the kidney is theoretically safer than the percutaneous approach because the needle passes from the venous system into the renal parenchyma and is directed away from large blood vessels. In addition, it is suggested that any bleeding that occurs should be directed back into the venous system, and if capsular perforation develops, significant bleeding points can be immediately identified and controlled by coil embolization. Others argue that coil embolization of the punctured vein is unhelpful because significant bleeding into either a perirenal hematoma or the urine indicates an arterial breach that requires selective angiography and arterial embolization.

Transvenous renal biopsy cannot be regarded as routine because it involves specialist skills and additional time and expense compared with the percutaneous approach. The main indication for this approach is an uncontrollable bleeding diathesis. It has also been advocated for use in a variety of other situations: patients receiving artificial ventilation in the intensive care unit; the need to obtain tissue from more than one organ, including the kidney, liver, or heart; large-volume ascites that precludes the prone position; uncontrolled hypertension; morbid obesity; severe respiratory insufficiency; solitary kidney; failed percutaneous approach; and coma.

The patient lies supine, and the right internal jugular vein is cannulated. A guide wire is passed into the inferior vena cava, and a catheter is passed over the guide wire and selectively into the right renal vein (the right renal vein is shorter and enters the vena cava at a more favorable angle than the left). A sheath is passed over the catheter to a suitable peripheral location in the kidney with the aid of contrast enhancement. Finally, the biopsy device (usually a side-cut biopsy needle system) is passed through the sheath and samples are taken. Contrast material is then injected into the biopsy track to identify capsular perforation, and embolization coils are inserted if brisk bleeding is identified.

The quality of renal tissue obtained by transjugular biopsy is variable, although studies report diagnostic yields of more than 90%.¹⁴ The complication rate appears comparable to that seen with percutaneous renal biopsy, which is reassuring given that these are high-risk patients.

Open Renal Biopsy

This has been established as a safe alternative to percutaneous biopsy when uncorrectable contraindications exist. The largest study reported a series of 934 patients in which tissue adequacy was 100% with no major complications.¹⁵ Nonetheless, although this is an effective approach with minimal postprocedure complications, the risk of general anesthesia and the delayed recovery time have prevented its widespread adoption. It may still, however, be performed when a renal biopsy is required in patients who are otherwise undergoing an abdominal surgical procedure.

Laparoscopic Renal Biopsy

This procedure requires general anesthesia and two laparoscopic ports in the posterior and anterior axillary lines to gain access to

Complications of Renal Biopsy		
	1952–1977 (%)	1990 to Present (%)
Number	14,492	4,542
Hematoma	1	4.6
Gross hematuria	3	4.6
Arteriovenous fistula	0.1	0.18
Surgery	0.3	1 case
Death	0.12	1 case

the retroperitoneal space. Laparoscopic biopsy forceps are used to obtain cortical biopsy samples, and the biopsy sites are coagulated with laser and packed to prevent hemorrhage. In the most recent and largest study, adequate tissue was obtained in 96% of the 74 patients included.¹⁶ Significant bleeding occurred in three patients, the colon was injured in one, and a biopsy was performed inadvertently on the spleen and liver, respectively, in two others. This last complication was subsequently averted by the use of intraoperative ultrasound to define the anatomy in difficult cases.

COMPLICATIONS OF RENAL BIOPSY

The complication rates compiled from large series of renal biopsies are shown in Figure 6.9.

Pain

A dull ache around the needle entry site is inevitable when the local anesthetic wears off, and patients should be warned about this. Simple analgesia with paracetamol or paracetamol-codeine combinations usually suffices. More severe pain in the loin or abdomen on the side of the biopsy raises the possibility of a significant perirenal hemorrhage. Opiates may be necessary for pain relief, and appropriate investigations to clarify the severity of the bleed should be performed. Patients with macroscopic hematuria may develop clot colic and describe the typical severe pain associated with ureteral obstruction.

Hemorrhage

A degree of perirenal bleeding accompanies every renal biopsy. The mean decrease in hemoglobin after a biopsy is approximately 1 g/dl.¹⁷ Significant perirenal hematomas are almost invariably associated with severe loin pain. Both macroscopic hematuria and painful hematoma are seen in 3% of patients after biopsy. The initial management is strict bed rest and maintenance of normal coagulation indices. If bleeding is brisk and associated with hypotension or prolonged and fails to settle with bed rest, renal angiography should be performed to identify the source of bleeding. Coil embolization can be performed during the same procedure, and this has largely eliminated the need for open surgical intervention and nephrectomy.

Arteriovenous Fistula

Most postbiopsy arteriovenous fistulas are detected by Doppler ultrasound or contrast-enhanced computed tomography and, when looked for specifically, can be found in as many as 18% of patients. Because most are clinically silent and more than 95% resolve spontaneously within 2 years, they should not be routinely sought. In a small minority, they can lead to macroscopic hematuria (typically recurrent, dark red, and often with blood clots), hypertension, and renal impairment, in which case, embolization is indicated.

Other Complications

A variety of other rare complications have been reported, including biopsy inadvertently performed on other organs (liver, spleen, pancreas, bowel, and gallbladder), pneumothorax, hemothorax, calyceal-peritoneal fistula, dispersion of carcinoma, and the Page kidney. This last complication results from compression of the kidney by a perirenal hematoma leading to renin-mediated hypertension.

Death

Death resulting directly from renal biopsy has become much less common according to recent biopsy series compared with earlier reports. Most deaths are the result of uncontrolled hemorrhage in high-risk patients, particularly those with severe renal impairment.

Disorders of Extracellular Volume

Elwaleed A. Elhassan, Robert W. Schrier

THE EXTRACELLULAR FLUID COMPARTMENT

Water is the predominant constituent of the human body. In healthy individuals, it makes up 60% of a man's body weight and 50% of a woman's body weight. Body water is distributed in two compartments, the intracellular fluid (ICF) compartment, containing 55% to 65%, and the extracellular fluid (ECF) compartment, containing the remaining 35% to 45%. The ECF is further subdivided into the interstitial space and the intravascular space. The interstitial space comprises approximately three fourths of ECF, whereas the intravascular space contains one fourth (Fig. 7.1).

Total body water diffuses freely between the intracellular space and the extracellular spaces in response to solute concentration gradients. Therefore, the amount of water in different compartments depends entirely on the quantity of solute in that compartment. The major solute in the ECF is sodium; potassium is the major intracellular solute. The maintenance of this distribution is fulfilled by active transport through the Na^+, K^+ -ATP-dependent pumps on the cell membrane, and this determines the relative volume of different compartments. Because sodium is the predominant extracellular solute, the ECF is determined primarily by the sodium content of the body and the mechanisms responsible for maintaining it. The amount of sodium is therefore very tightly regulated by modulation of renal retention and excretion in situations of deficient and excess ECF, respectively.

Fluid movement between the intravascular and interstitial compartments of the ECF occurs across the capillary wall and is governed by the Starling forces, namely, the capillary hydrostatic pressure and colloid osmotic pressure. The transcapillary hydrostatic pressure gradient exceeds the corresponding oncotic pressure gradient, thereby favoring movement of plasma ultrafiltrate into the extravascular space. The return of fluid into the intravascular compartment occurs through lymphatic flow.

Maintaining the ECF volume determines the adequacy of the circulation and, in turn, the adequacy of delivery of oxygen, nutrients, and other substances needed for organ functions as well as for removal of waste products. This is achieved in spite of day-to-day variations in the intake of sodium and water, with the ECF volume varying by only 1% to 2%.

Effective Arterial Blood Volume

This term is used to describe the blood volume that is detected by the sensitive arterial baroreceptors in the arterial circulation. The effective arterial blood volume (EABV) can change independently of the total ECF volume and can explain the sodium and water retention in different health and disease clinical situations (see later discussion).

REGULATION OF EXTRACELLULAR FLUID HOMEOSTASIS

Circulatory stability depends on a meticulous degree of ECF homeostasis. The operative homeostatic mechanisms include an afferent sensing limb comprising several volume and stretch detectors distributed throughout the vascular bed and an efferent effector limb. Adjustments in the effector mechanisms occur in response to afferent stimuli by sensing limb detectors with the aim of modifying circulatory parameters. Disorders of either sensing or effector mechanisms can lead to failure of adjustment of sodium handling by the kidney with resultant hypertension or edema formation in the case of positive sodium balance or hypotension and hypovolemia in the case of negative sodium balance.

The Afferent (Sensor) Limb

Afferent limb sensing sites include low-pressure cardiopulmonary receptors (atrial, ventricular, and pulmonary stretch receptors), high-pressure arterial baroreceptors (carotid, aortic arch, and renal sensors), central nervous system (CNS) receptors, and hepatic receptors (Fig. 7.2). The cardiac atria possess the distensibility and the compliance needed to monitor changes in intrathoracic venous volume. An increase in left atrial pressure suppresses the release of the antidiuretic hormone arginine vasopressin (AVP). Atrial distention and a sodium load cause release into the circulation of atrial natriuretic peptide (ANP), a polypeptide normally stored in secretory granules within atrial myocytes. The closely related brain natriuretic peptide (BNP) is stored primarily in ventricular myocardium and is released when ventricular diastolic pressure rises. The atrial-renal reflexes aim to enhance renal sodium and water excretion on sensing of a distended left atrium.

The sensitive arterial stretch receptors in the carotid artery, aortic arch, and glomerular afferent arteriole respond to a decrease in arterial pressure. Information from these nerve endings is carried by the vagal and glossopharyngeal nerves to vasomotor centers in the medulla and brainstem. In the normal situation, the prevailing discharge from these receptors exerts a tonic restraining effect on the heart and circulation by inhibiting the sympathetic outflow and augmenting parasympathetic activity. In addition, changes in transmural pressure across the arterial vessels and the atria also influence the secretion of AVP and renin and the release of ANP. Activation of the arterial receptors signals the kidney to retain sodium and water by increases in the sympathetic activity and by increases in vasopressin release. Stimulation of the sympathetic nervous system also enhances the renin-angiotensin-aldosterone system (RAAS). A rise in arterial

Figure 7.1 Composition of body fluid compartments. Schematic representation of body fluid compartments in humans. The shaded areas depict the approximate size of each compartment as a function of body weight. The figures indicate the relative sizes of the various fluid compartments and the approximate absolute volumes of the compartments (in liters) in a 70-kg adult. Intracellular electrolyte concentrations are in millimoles per liter and are typical values obtained from muscle. ECF, extracellular fluid; ICF, intracellular fluid; ISF, interstitial fluid; IVF, intravascular fluid; TBW, total body water. (From reference 1. Reproduced with permission of Hodder Arnold.)

pressure elicits the opposite response, resulting in decreased catecholamine release and natriuresis.

Renal sensing mechanisms include the juxtaglomerular apparatus, which is involved in the generation and release of renin from the kidney. Renin secretion is inversely related to perfusion pressure and directly related to intrarenal tissue pressure. Solute delivery to the macula densa is also an important determinant of renin release by way of the tubuloglomerular feedback (TGF) mechanism; an increase in chloride passage through the macula densa results in inhibition of renin release, whereas a decrease in concentration results in enhanced secretion of renin. Renal nerve stimulation through activation of β -adrenergic receptors of the juxtaglomerular apparatus cells directly stimulates renin release. Other receptors reside in the CNS and hepatic circulation but have been less well defined.

Efferent (Effector) Limb

The stimulation of the effector limb of the ECF volume homeostasis leads to activation of effector mechanisms (see Fig. 7.2). These effector mechanisms aim predominantly at modulation of renal sodium and water excretion to preserve circulatory stability.

Major Effector Homeostatic Mechanisms	
Afferent	Efferent
Cardiopulmonary receptors Atrial Ventricular Pulmonary	Renal-angiotensin-aldosterone system
High-pressure baroreceptors Carotid Aortic Renal Glomerular afferent Juxtaglomerular apparatus	Prostaglandins
Central nervous system receptors	Arginine vasopressin
Hepatic receptors	Natriuretic peptides ANP BNP CNP Other hormones – NO Endothelin Kallikrein-kinin system

Figure 7.2 Major effector homeostatic mechanisms. ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide; CNP, C-type natriuretic peptide; NO, nitric oxide.

Sympathetic Nervous System

Sympathetic nerves that originate in the prevertebral celiac and paravertebral ganglia innervate cells of the afferent and efferent arterioles, juxtaglomerular apparatus, and renal tubule. Sympathetic nerves alter renal sodium and water handling by direct and indirect mechanisms.² Increased nerve stimulation indirectly stimulates proximal tubular sodium reabsorption by altering preglomerular and postglomerular arteriolar tone, thereby influencing filtration fraction. Renal nerves directly stimulate proximal tubular fluid reabsorption through receptors on the basolateral membrane of the proximal convoluted tubule cells. These effects on sodium handling are further amplified by the ability of the sympathetic nerves to stimulate renin release, which leads to the formation of angiotensin II (Ang II) and aldosterone.

Renin-Angiotensin-Aldosterone System

Renin formation by the juxtaglomerular apparatus increases in response to the aforementioned ECF homeostatic afferent limb stimuli. Renin converts angiotensinogen to angiotensin I, which is then converted to Ang II by the action of angiotensin-converting enzyme (ACE); Ang II can subsequently affect circulatory stability and volume homeostasis. It is an effective vasoconstrictor and modulator of renal sodium handling mechanisms at multiple nephron sites. Ang II preferentially increases the efferent arteriolar tone and hence affects the glomerular filtration rate (GFR) and filtration fraction by altering Starling forces across the glomerulus, which leads to enhanced proximal sodium and water retention. Ang II also augments sympathetic neurotransmission and enhances the TGF mechanism. In addition to these indirect mechanisms, Ang II directly enhances proximal tubular volume reabsorption by activating apical membrane sodium-hydrogen exchangers. In addition to a nephron effect, Ang II enhances sodium absorption by stimulating the adrenal gland to secrete aldosterone, which in turn increases sodium reabsorption in the cortical collecting tubule.

Prostaglandins

Prostaglandins are proteins derived from arachidonic acid that modulate renal blood flow and sodium handling. Important renal prostaglandins include PGI₂, which mediates baroreceptor (but not β -adrenergic) stimulation of renin release. PGE₂ is stimulated by Ang II and has vasodilatory properties secondary to total blood volume or EABV contraction. Increased level of Ang II, AVP, and catecholamines stimulates synthesis of prostaglandins, which in turn act to dilate the renal vasculature, to inhibit sodium and water reabsorption, and further to stimulate renin release. By doing so, renal prostaglandins serve to dampen and counterbalance the physiologic effects of the hormones that elicit their production and so maintain renal function. Inhibition of prostaglandins by nonsteroidal anti-inflammatory drugs (NSAIDs) leads to magnification of the effect of vasoconstricting hormones and unchecked sodium and water retention.

Arginine Vasopressin

AVP is a polypeptide synthesized in supraoptic and paraventricular nuclei of the hypothalamus and is secreted by the posterior pituitary gland. Besides osmotic control of AVP release, a nonosmotic regulatory pathway sensitive to EABV exists.³ AVP release is suppressed in response to ECF volume overload sensed by increased afferent impulses from arterial baroreceptors and atrial receptors, whereas decreased ECF volume has the opposite effect. AVP release leads to antidiuresis and, in high doses, to systemic vasoconstriction through the V₁ receptors.⁴ The antidiuretic action of AVP is the result of the effect on the principal cell of the collecting duct through activation of the V₂ receptor. AVP increases the synthesis and provokes the insertion of aquaporin 2 water channels into the luminal membrane, thereby allowing water to be reabsorbed down the favorable osmotic gradient. AVP may also lead to enhanced reabsorption of sodium and the secretion of potassium. AVP appears to have synergistic effects with aldosterone on sodium transport in the cortical collecting duct.⁵ AVP stimulates potassium secretion by the distal nephron, and this serves to preserve potassium balance during ECF depletion, when circulating levels of vasopressin are high and tubular delivery of sodium and fluid is reduced.

Natriuretic Peptides

ANP is a polypeptide hormone that stimulates diuresis, natriuresis, and vasorelaxation. ANP is primarily synthesized in the cardiac atria and released in response to a rise in atrial distention. ANP augments sodium and water excretion by increasing the GFR, possibly by dilating the afferent arteriole and constricting the efferent arteriole. Furthermore, it inhibits sodium reabsorption in the cortical collecting tubule and inner medullary collecting duct, reduces renin and aldosterone secretion, and opposes the vasoconstrictive effects of Ang II. BNP is another natriuretic hormone that is produced in the cardiac ventricles. It induces natriuretic, endocrine, and hemodynamic responses similar to those induced by ANP.⁶ Circulating levels of ANP and BNP are elevated in congestive heart failure (CHF) and in cirrhosis with ascites, but not to levels sufficient to prevent edema formation. In addition, in those edematous states, there is resistance to the actions of natriuretic peptides.

C-type natriuretic peptide (CNP) is produced by endothelial cells, where it is believed to play a role in the local regulation of vascular tone and blood flow. However, its physiologic significance in the regulation of sodium and water balance in humans is not well defined.

Other Hormones

Several other hormones contribute to renal sodium handling and ECF volume homeostasis. They include nitric oxide, endothelin, and the kallikrein-kinin system. Nitric oxide is an endothelium-derived mediator that has been shown to participate in the natriuretic responses to increases in blood pressure or ECF volume expansion, so-called pressure natriuresis. Endothelins are natriuretic factors and kinins are potent vasodilator peptides whose physiologic roles are yet to be fully defined.

EXTRACELLULAR FLUID VOLUME CONTRACTION

ECF volume contraction refers to a decrease in ECF volume caused by sodium or water loss exceeding intake. Losses may be renal or extrarenal through the gastrointestinal tract, skin, and lungs or by sequestration in potential spaces in the body (e.g., abdomen, muscle) that are not in hemodynamic equilibrium with the ECF (Fig. 7.3). The reduction in ECF volume occurs simultaneously from both the interstitial and intravascular compartments and is determined by whether the volume loss is primarily solute-free water or a combination of sodium and water. The loss of solute-free water has a lesser effect on intravascular volume because of the smaller amount of water present in the ECF compared with the ICF and the free movement of water between fluid compartments.

Extrarenal Causes

Gastrointestinal Losses

Approximately 3 to 6 liters of fluids and digestive juices are secreted daily throughout the gastrointestinal tract, and most of this fluid is reabsorbed. Vomiting or nasogastric suction may cause volume loss that is usually accompanied by metabolic alkalosis, whereas diarrhea may result in volume depletion that is accompanied by metabolic acidosis.

Dermal Losses

Sweat production can be excessive in high ambient temperature or with prolonged exercise in hot, humid climates and may lead to volume depletion. Loss of the skin barrier with superficial burns and exudative skin lesions may lead to significant ECF volume depletion.

Third-Space Sequestration

Body fluid accumulation in potential spaces that are not in hemodynamic equilibrium with the ECF compartment can cause volume depletion. This pathologic accumulation is often referred to as third-space sequestration and includes ascites, hydrothorax, and intestinal obstruction, whereby fluid collects in the peritoneal cavity, pleural space, or intestines, respectively, and leads to significant ECF volume loss. Severe pancreatitis may result in retroperitoneal fluid collections.

Hemorrhage

Hemorrhage occurring internally, such as from bleeding esophageal varices, or externally as a result of trauma may lead to significant volume loss.

Renal Losses

In the normal individual, about 25,000 mmol of sodium is filtered every day, and a small amount of that quantity is excreted in the urine. The small quantities of sodium excreted in urine

Figure 7.3 Major causes of extracellular fluid volume depletion.

relative to the filtered load depend on intact tubular reabsorptive mechanisms to adjust urinary sodium excretion according to the degree needed to maintain ECF homeostasis. Impairment in the integrity of these sodium reabsorptive mechanisms can result in a significant sodium deficit and volume depletion.

Diuretic Use

Most of the widely used diuretic medications inhibit specific sites for sodium reabsorption at different segments of the nephron. These agents may cause renal sodium wasting, volume contraction, and metabolic acid-base disturbances if they are abused or inappropriately prescribed. Ingestion of osmotic diuretics results in obligatory renal sodium and water loss. Further discussion of diuretics is presented at the end of the chapter.

Genetic and Acquired Tubular Disorders

(see Chapters 47 and 48)

Tubular sodium reabsorption may be disrupted in several genetic disorders, such as Bartter syndrome and Gitelman's syndrome, which are autosomal recessive disorders caused by mutations of sodium transporters that are targets of diuretics or other transporters that are their essential cellular partners. Both conditions result in sodium wasting, volume contraction, and hypokalemic metabolic alkalosis.⁷ Pseudohypoaldosteronism type 1 is a rare inherited disorder characterized by renal sodium wasting and hyperkalemic metabolic acidosis. Acquired tubular disorders that may be accompanied by sodium wasting include acute kidney injury during the recovery phase of oliguric acute kidney injury or urinary obstruction.

Hormonal and Metabolic Disturbances

Mineralocorticoid deficiency and resistance states often lead to sodium wasting. This may occur in the setting of primary adrenal insufficiency (Addison's disease) or with hyporeninemic hypoaldosteronism secondary to diabetes mellitus or other chronic

interstitial renal diseases. Severe hyperglycemia or high levels of blood urea during release of urinary tract obstruction can lead to obligatory renal sodium and water loss secondary to glucosuria or urea diuresis, respectively.

Renal Water Loss

Diabetes insipidus represents a spectrum of diseases resulting from AVP deficiency or tubular resistance to the actions of AVP. In these disorders, the tubular reabsorption of solute-free water is impaired. This generally results in a lesser effect on ECF volume because a relatively smaller amount of the total body water, in contrast to sodium, exists in the ECF compartment compared with the ICF compartment.

Clinical Manifestations

The spectrum of the clinical manifestations of volume contraction depends on the amount and rate of volume loss as well as on the vascular and renal responses to that loss. An adequate history and physical examination are crucial to elucidate the cause of hypovolemia. Symptoms are usually nonspecific and can range from mild postural symptoms, thirst, muscle cramps, and weakness to drowsiness and disturbed mentation with profound volume loss. Physical examination may reveal tachycardia, cold clammy skin, postural or recumbent hypotension, and reduced urine output, depending on the degree of volume loss (Fig. 7.4). Reduced jugular venous pressure (JVP) noted at the base of the neck is a useful parameter of volume depletion and may roughly estimate the central venous pressure (CVP). However, an elevated CVP does not exclude hypovolemia in patients with underlying cardiac failure or pulmonary hypertension. The lack of symptoms or discernible physical findings does not preclude volume depletion in an appropriate clinical setting, and hemodynamic monitoring and administration of a fluid challenge may sometimes be necessary.

Clinical Evaluation of Extracellular Fluid Volume Depletion

Mild to moderate volume loss

Thirst
 Delay in capillary refill
 Postural dizziness, weakness
 Dry mucous membranes and axillae
 Cool clammy extremities and collapsed peripheral veins
 Tachypnea
 Tachycardia with pulse rate >100 beats per minute or postural pulse increment of 30 beats/min or more
 Postural hypotension (systolic blood pressure decrease of >20 mm Hg with standing)
 Low jugular venous pulse
 Oliguria

Severe volume loss and hypovolemic shock

Depressed mental status (or loss of consciousness)
 Peripheral cyanosis
 Reduced skin turgor (in young patients)
 Marked tachycardia, low pulse volume
 Supine hypotension (systolic blood pressure <100 mm Hg)

Figure 7.4 Clinical evaluation of extracellular fluid volume depletion.

Laboratory Indices

Laboratory parameters may assist in defining the underlying causes of volume depletion. Hemoconcentration and increased serum albumin concentration may be seen early with hypovolemia, but anemia or hypoalbuminemia caused by a concomitant disease may confound interpretation of these laboratory values. In healthy individuals, the blood urea nitrogen (BUN)/serum creatinine ratio is approximately equal to 10 mg/dl (40 mmol/l). In volume-contracted states, this ratio may significantly increase because of an associated differential increase in urea reabsorption in the collecting duct. Several clinical conditions affect this ratio. Upper gastrointestinal hemorrhage and administration of corticosteroids increase urea production, and hence the BUN/creatinine ratio increases. Malnutrition and underlying liver disease diminish urea production, and thus the ratio is less helpful to support volume depletion in such clinical settings.

Urine osmolality and specific gravity may be elevated in hypovolemic states but may be altered by an underlying renal disease that leads to renal sodium wasting, concomitant intake of diuretics, or a solute diuresis. Hypovolemia normally promotes avid renal sodium reabsorption, resulting in low urine sodium concentration and low fractional excretion of sodium. Urine chloride follows a similar pattern because sodium and chloride are generally reabsorbed together. Volume depletion with metabolic alkalosis (e.g., with vomiting) is an exception because of the need to excrete the excess bicarbonate in conjunction with sodium to maintain electroneutrality; in that case, the urine chloride concentration is a better index of sodium avidity. The fractional excretion of sodium (FE_{Na}) is calculated by the following formula:

$$FE_{Na} = [U_{Na} \times P_{creat} / U_{creat} \times P_{Na}] \times 100$$

where U_{Na} and U_{creat} are urinary sodium and creatinine concentrations, respectively, and P_{Na} and P_{creat} are serum sodium and creatinine concentrations, respectively. Elevated (>1) FE_{Na} is most helpful in the diagnosis of acute kidney injury; FE_{Na} of less than 1% is consistent with volume depletion.

Therapy for Extracellular Volume Contraction

The goals of treatment of ECF volume depletion are to replace the fluid deficit and to replace ongoing losses, in general, with a replacement fluid that resembles the lost fluid. The first step is estimating the magnitude of volume loss. Helpful tools include the clinical parameters for mild to moderate versus severe volume loss (see Fig 7.4), which can also be assessed by invasive monitoring when necessary. The initial replacement volume is then determined and delivered with an administration rate that is tailored as subsequently judged by frequent monitoring of clinical parameters. Mild volume contraction can usually be corrected through the oral route. In cases of hypovolemic shock with evidence of life-threatening circulatory collapse or organ dysfunction, intravenous fluid must be administered as rapidly as possible until clinical parameters improve. However, in most cases, a slow, more careful approach is warranted, particularly in the elderly and in patients with an underlying cardiac condition, to avoid overcorrection with subsequent pulmonary or peripheral edema. Crystalloid solutions with sodium as the principal cation are effective as they distribute primarily in the ECF. A third of an infusate of isotonic saline remains in and expands the intravascular compartment; two thirds distributes into the interstitial compartment. Colloid-containing solutions include human albumin (5% and 25% albumin) and hetastarch (6% hydroxyethyl starch). Because of large molecular size, these solutions remain within the vascular compartment, provided the transcapillary barrier is intact and not disrupted by capillary leak states, such as often occurs with multiorgan failure or systemic inflammatory response syndrome. They augment the plasma oncotic pressure and thus expand the plasma volume by counteracting the capillary hydraulic pressure. Studies have not shown an advantage for colloid-containing solutions in the treatment of hypovolemic states. A meta-analysis of 55 studies showed no outcome difference between critically ill patients who received albumin and those who received crystalloids.⁸ Furthermore, a large multicenter trial that randomized medical and surgical critical patients to receive fluid resuscitation with 4% albumin or normal saline showed similar mortality, measured morbidity parameters, and hospitalization rates in the two groups.⁹ Consequently, timely administration of a sufficient quantity of intravenous fluids is more important than the type of fluid chosen. However, because of the higher cost of colloids, these are best reserved for hemodynamically unstable patients in whom rapid correction is needed, such as trauma and burns victims. Otherwise, isotonic saline is usually the initial choice in volume-depleted patients with normal serum sodium concentration and most of those with low serum sodium concentration. Furthermore, isotonic saline is the preferred fluid to restore ECF volume in hypovolemic patients with hypernatremia. Once euolemia is established, further fluid therapy should be delivered to gradually correct tonicity in the form of hypotonic (0.45%) saline. Administration of large volumes of isotonic saline may result in elevation of serum sodium above the normal range because it is slightly hypertonic (155 mmol/l) compared with plasma. If that happens, hypotonic saline can be continued instead, until volume is replete. Hypokalemia may be present initially or may subsequently ensue. It should be corrected by adding appropriate amounts of potassium chloride to replacement solutions.

Hypovolemic shock may be accompanied by lactic acidosis due to tissue hypoperfusion. Fluid resuscitation restores tissue oxygenation and will decrease the production of lactate. Correction of acidosis with sodium bicarbonate has the potential for

increasing tonicity, expanding volume, worsening intracellular acidosis from increased carbon dioxide production, and not improving hemodynamics compared with isotonic saline. Use of sodium bicarbonate for correction of cardiac contractility coexisting with lactic acidosis has not been well documented by clinical studies. Therefore, its use to manage lactic acidosis in the setting of volume depletion is not recommended (unless the arterial pH is below 7.1).

EXTRACELLULAR FLUID VOLUME EXPANSION

Definition

ECF volume expansion refers to excess fluid accumulation in the ECF compartment, usually resulting from sodium and water retention by the kidneys. Generalized edema results when an apparent increase in the interstitial fluid volume takes place. It may occur in disease states most commonly in response to cardiac failure, cirrhosis with ascites, and the nephrotic syndrome. Weight gain of several liters usually precedes clinically apparent edema. Localized excess fluid may accumulate in the peritoneal and pleural cavities, giving rise to ascites and pleural effusion, respectively.

Pathogenesis

Renal sodium and water retention secondary to arterial underfilling leads to an alteration in capillary hemodynamics that favors fluid movement from the intravascular compartment into the interstitium. In general, these two processes account for edema formation.

Capillary Hemodynamic Disturbances

According to the Starling equation, the exchange of fluid between the plasma and the interstitium is determined by the hydrostatic and oncotic pressures in each compartment. Interstitial fluid excess results from a decrease in plasma oncotic pressure or an increase in capillary hydrostatic pressure. In other words, edema is a result of an increase of fluid movement from the intravascular compartment to the interstitial space, a decrease in fluid movement from the interstitial space to the intravascular compartment, or both. Thus, the degree of interstitial fluid accumulation as determined by the rate of fluid removal by the lymphatic vessels is a determinant of edema.

The capillary hydrostatic pressure is relatively insensitive to alterations in arterial pressure. The stability of the capillary pressure is due to variations in the precapillary sphincter, which governs how much arterial pressure is transmitted to the capillary, a response called autoregulation that is locally controlled. In contrast, the venous end is not similarly well regulated. Therefore, when the blood volume is expanded, such as in CHF and renal disease, capillary hydrostatic pressure increases and edema ensues. Venous obstruction works by the same mechanism to cause edema as exemplified, at least partially, by ascites formation in liver cirrhosis and by acute pulmonary edema after sudden impairment in cardiac function (as with myocardial infarction). In hepatic cirrhosis and nephrotic syndrome, another factor in edema formation is reduction in plasma oncotic pressure with a tendency for fluid transudation into the interstitial space. The balance of the Starling forces acting on the capillary favors the net filtration into the interstitium because capillary hydrostatic pressure exceeds the plasma colloid pressure, in several tissues, throughout the length of the capillary. In these

tissues, a substantial amount of filtered fluid is returned to the circulation through lymphatics, which serve as a protective mechanism for minimizing edema formation.

Renal Sodium Retention

The mechanism for maintenance of ECF volume expansion and edema formation is renal sodium retention, which can be primary or secondary in response to reduction in EABV (Fig. 7.5).

Primary Renal Sodium Retention A primary defect in renal sodium excretion can occur with both acute and chronic renal failure and with glomerular disease. Patients with acute kidney injury have a limited ability to excrete sodium and water. Advanced chronic kidney disease may lead to sodium and water retention by GFR reduction secondary to a decrease in functioning nephrons. Some forms of glomerulonephritis are characterized by primary renal sodium retention. This happens by incompletely understood mechanisms in the presence of a relatively suppressed RAAS but frequently with a decreased GFR. States of mineralocorticoid excess or enhanced activity are associated with a phase of sodium retention. However, because of the phenomenon of “mineralocorticoid escape,” the clinical manifestation is generally hypertension rather than hypervolemia. In normal subjects, administration of a high dose of mineralocorticoid initially increases renal sodium retention so that the volume of ECF is increased. However, renal sodium retention then ceases, spontaneous diuresis ensues, sodium balance is reestablished, and there is no detectable edema. This escape from mineralocorticoid-mediated sodium retention explains why edema is not a characteristic feature of primary hyperaldosteronism. The pathophysiologic mechanism of the mineralocorticoid escape phenomenon involves an increase in GFR and reduction of proximal tubular sodium and water reabsorption. This leads to an increase in sodium and water delivery to the distal nephron site of aldosterone action, which overrides the sodium reabsorption of aldosterone. Other mechanisms believed to account for this phenomenon involve decreased expression of distal tubular sodium transporters,¹⁰ increased secretion of ANP induced by the hypervolemia,¹¹ and pressure natriuresis. Pressure natriuresis refers to the phenomenon whereby increasing renal perfusion pressure (due in part to systemic hypertension) enhances sodium excretion. These mechanisms act by decreasing tubular reabsorption at sites other than the aldosterone-sensitive cortical collecting duct.

Mechanisms by Which Cardiac Failure Leads to the Activation of Neurohormonal Vasoconstrictor Systems and Renal Sodium and Water Retention

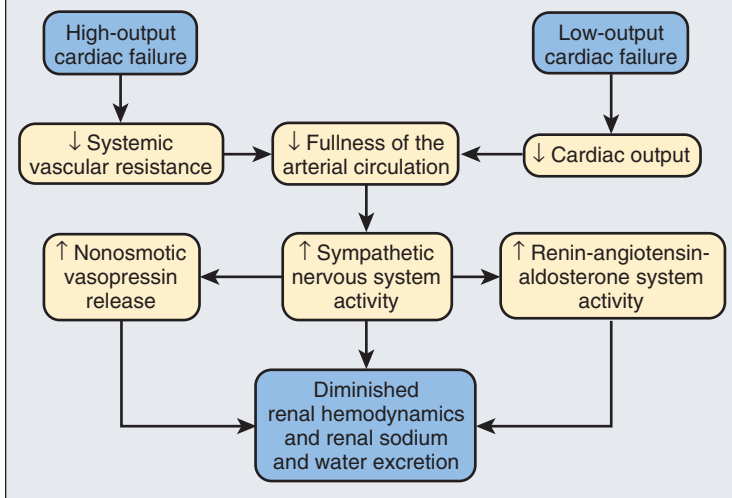

Figure 7.6 Mechanisms by which cardiac failure leads to the activation of neurohormonal vasoconstrictor systems and renal sodium and water retention. (Modified from reference 12.)

Renal Sodium Retention as a Compensatory Response to Effective Arterial Blood Volume Depletion (Arterial Underfilling)

PATHOPHYSIOLOGY OF ARTERIAL UNDERFILLING A unifying hypothesis elucidating the mechanisms by which the kidneys perceive arterial blood volume depletion and subsequently retain sodium and water in relevant clinical situations has been proposed and supported.¹³ Estimates of blood volume distribution indicate that 85% of blood circulates on the low-pressure, venous side of the circulation, whereas an estimated 15% of blood is circulating in the high-pressure, arterial circulation. Thus, an increase in total blood volume could occur, even when there is underfilling of the arterial circulation, if the increase in total blood volume is primarily due to expansion of the venous compartment. Underfilling of the arterial circulation could occur secondary to either a decrease in cardiac output, as occurs in low-output cardiac failure, or systemic arterial vasodilation, which occurs early in cirrhosis as a result of diminished vascular resistance in the splanchnic circulation. This hypothesis proposes that the events triggered by arterial underfilling as a result of either a decrease in cardiac output or systemic arterial vasodilation (Fig. 7.6) are compensatory responses necessary to restore arterial circulatory integrity.

RENAL RESPONSE TO ARTERIAL UNDERFILLING If there is arterial underfilling, either due to a decrease in cardiac output or due to systemic arterial vasodilation, the underfilling is sensed by the arterial stretch receptors. This leads to activation of the efferent limb of body fluid volume homeostasis. Specifically, a decrease in glossopharyngeal and vagal tone from the carotid and aortic receptors to the CNS leads to a rapid increase in sympathetic activity with associated activation of the RAAS axis and nonosmotic release of vasopressin. The resultant increase in systemic vascular resistance and renal sodium and water retention attenuates the arterial underfilling and associated diminished arterial perfusion. The purpose of these concerted actions is to maintain the arterial circulatory integrity and restore the perfusion to the vital organs, which is mandatory for survival. Further discussion and explanation of how this mechanism

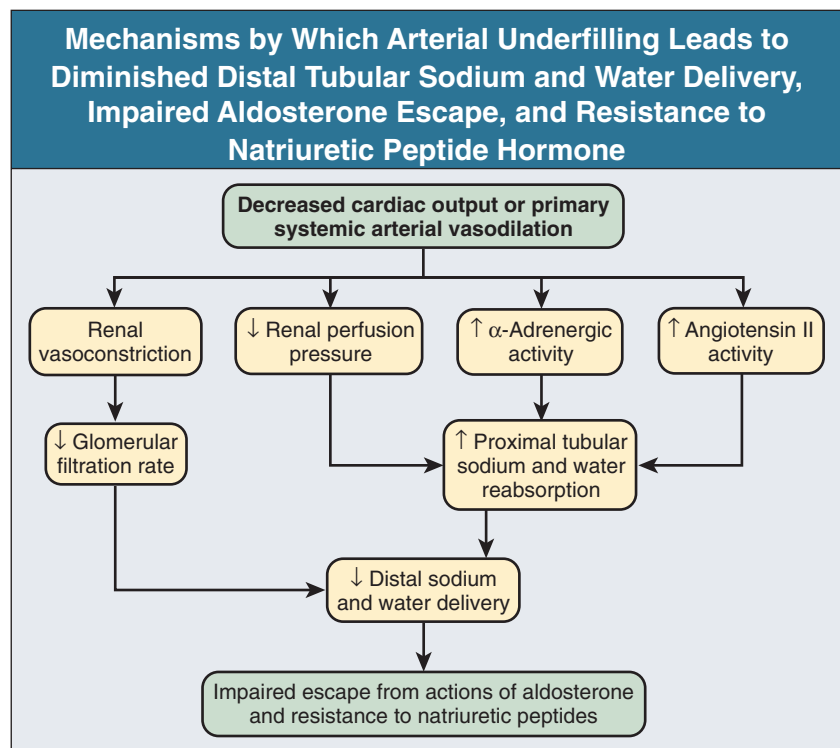

operates in cardiac failure, cirrhosis, and pregnancy are now discussed.

Sodium and Water Retention in Cardiac Failure

The renal sodium and water retention that occurs in CHF involves several mediators.¹⁴ Decreased cardiac output with arterial underfilling leads to reduced stretch of arterial baroreceptors. This results in increased sympathetic discharge from the CNS and resultant activation of the RAAS. Adrenergic stimulation and increased Ang II both activate receptors on the proximal tubular epithelium that enhance sodium reabsorption. The renal vasoconstriction of the glomerular efferent arteriole by Ang II in CHF also alters net Starling forces in the peritubular capillary in a direction to enhance sodium reabsorption.¹⁵ Thus, angiotensin and α -adrenergic stimulation increase sodium reabsorption in the proximal tubule by a direct effect on the proximal tubule epithelium and secondarily by renal vasoconstriction. This subsequently leads to decreased sodium delivery to the collecting duct, which is the major site of action of aldosterone and the natriuretic peptides. CHF patients experience renal resistance to natriuretic effects of atrial and ventricular peptides. The resultant decreased sodium delivery to the distal nephron impairs the normal escape mechanism from the sodium-retaining effect of aldosterone and impairs the effect of natriuretic peptides; taken together, these effects explain at least partially why sodium retention and ECF expansion occur in CHF (Fig. 7.7). Accordingly, CHF patients have substantial natriuresis when spironolactone, a competitive mineralocorticoid receptor antagonist, is given in adequate doses to compete with increased endogenous aldosterone levels.¹⁶

Another outcome of the neurohumoral activation that occurs in cardiac failure is the baroreceptor-mediated nonosmotic release of AVP.¹⁷ This nonosmotic AVP stimulation overrides the osmotic regulation of AVP and is the major factor leading to the hyponatremia associated with CHF.¹⁸ AVP causes antidiuresis by activating vasopressin V_2 receptors on the basolateral surface of the principal cells in the collecting duct.¹⁹ Activation of these receptors initiates a cascade of intracellular signaling events by means of the adenylyl cyclase-cyclic adenosine

Figure 7.7 Mechanisms by which arterial underfilling leads to diminished distal tubular sodium and water delivery, impaired aldosterone escape, and resistance to natriuretic peptide hormone. (Modified from reference 21.)

monophosphate pathway, leading to an increase in aquaporin 2 water channel protein expression and its trafficking to the apical membrane of the collecting duct. This sequence of events leads to increased water reabsorption and can cause hyponatremia, which is an ominous prognostic indicator in patients with heart failure.²⁰ Concurrently, increased nonosmotic AVP release stimulates V_1 receptors on vascular smooth muscle cells and thereby may increase systemic vascular resistance. This adaptive vasoconstrictive response may become maladaptive and contribute to cardiac dysfunction in patients with severe heart failure.

The atrial-renal reflexes, which normally enhance renal sodium excretion, are impaired during CHF because renal sodium and water retention occurs despite elevated atrial pressure. Moreover, in contrast to normal subjects, plasma levels of ANP were found not to increase further during a saline load in patients with dilated cardiomyopathy and mild heart failure, and the natriuretic response was also blunted. The attenuation of these reflexes on the low-pressure side of the circulation not only is attributable to a blunting of the atrial-renal reflexes but also may in part be caused by counteracting arterial baroreceptor-renal reflexes. Autonomic dysfunction and blunted arterial baroreceptor sensitivity in CHF occur and are associated with increased circulating catecholamines and increased renal sympathetic activity. There is also evidence for parasympathetic withdrawal in CHF in addition to the increase in sympathetic drive.

Sodium and Water Retention in Cirrhosis

In many aspects, there are similarities in the pathogenesis of sodium and water retention between cirrhosis and CHF (Fig. 7.8). The arterial underfilling in cirrhosis, however, occurs secondary to splanchnic arterial vasodilation, with resultant water and sodium retention. It is postulated that the initial event in ascites formation in cirrhotic patients is sinusoidal and portal hypertension.²² In cirrhotic patients, this is a consequence of distortion of hepatic architecture, increased hepatic vascular

tone, or increased splenohepatic flow. Decreased intrahepatic bioavailability of nitric oxide and increased production of vasoconstrictors such as angiotensin and endothelin also are responsible for increased resistance in the hepatic vasculature.²³ Portal hypertension due to increase in sinusoidal pressure activates vasodilatory mechanisms in the splanchnic circulation.²⁴ These mechanisms, mediated at least in part by nitric oxide and carbon monoxide overproduction, lead to splanchnic and peripheral arteriolar vasodilation. In advanced stages of cirrhosis, arteriolar vasodilation causes underfilling of the systemic arterial vascular space. This event, through a decrease in EABV, leads to a fall in arterial pressure. Consequently, baroreceptor-mediated activation of the RAAS, sympathetic nervous system stimulation, and nonosmotic release of antidiuretic hormone (ADH) occur to restore the normal blood volume homeostasis.²⁵ This involves compensatory vasoconstriction as well as renal sodium and water retention. However, splanchnic vasodilation also increases splanchnic lymph production, which exceeds the lymph transporting capacity, and thus lymph leakage into the peritoneal cavity occurs with ascites development.²⁶ Persistent renal sodium and water retention, along with increased splanchnic vascular permeability in addition to lymph leakage into the peritoneal cavity, plays the major role in a sustained ascites formation.

Sodium and Water Retention in Nephrotic Syndrome

Unlike CHF and liver cirrhosis, in which the kidneys are structurally normal, the nephrotic syndrome is characterized by diseased kidneys that are often functionally impaired. Nephrotic patients typically have a higher arterial blood pressure, higher GFR, and less impairment of sodium and water excretion than do patients with CHF and cirrhosis. Whereas edema is recognized as a major clinical manifestation of the nephrotic syndrome, its pathogenetic mechanism remains less clearly defined. Two possible explanations are the underfill and the overfill theories (Fig. 7.9). The underfill theory suggests that reduction in

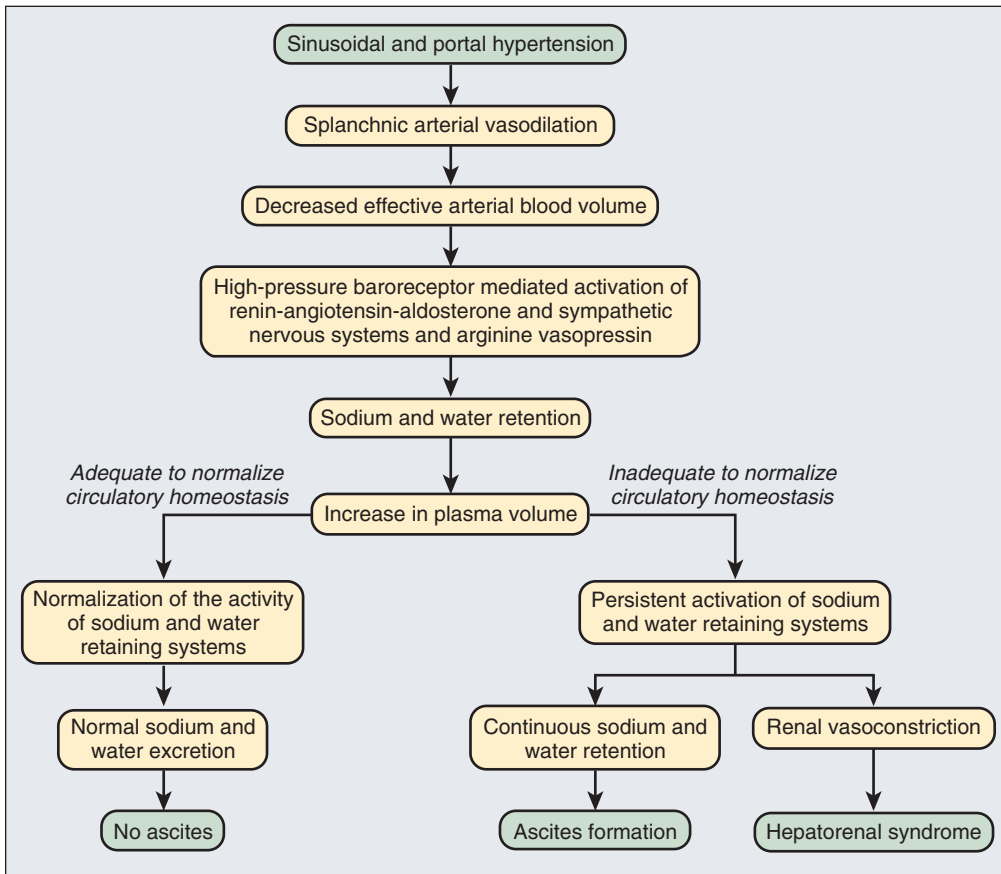

Figure 7.8 Pathogenesis of functional renal abnormalities and ascites formation in liver cirrhosis. (Modified from reference 27.)

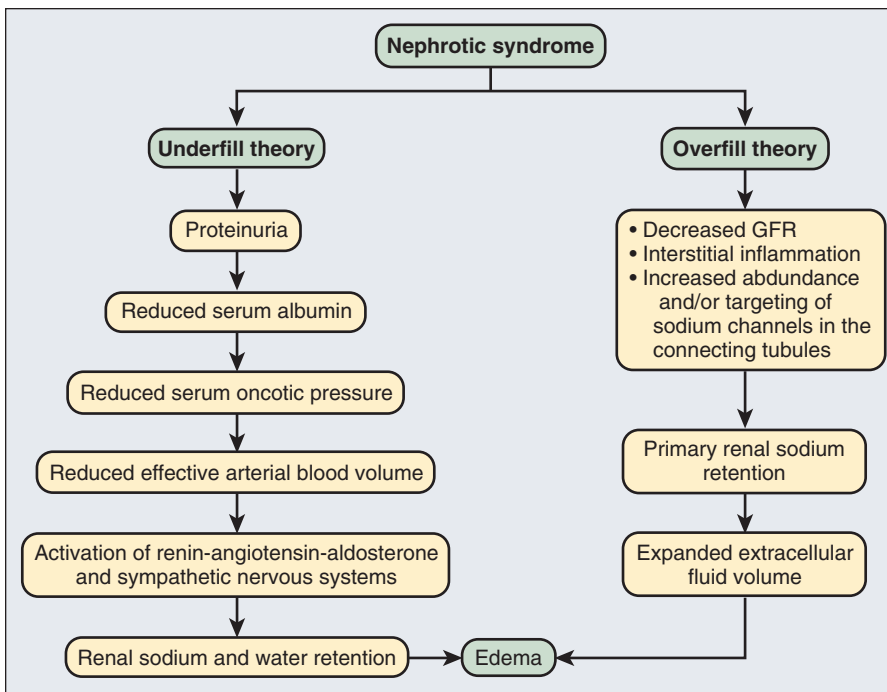

Figure 7.9 Pathogenesis of edema in the nephrotic syndrome.

the plasma oncotic pressure due to proteinuria causes an increase in fluid movement from the vascular to the interstitial compartment. The resultant arterial underfilling culminates in activation of homeostatic mechanisms involving the sympathetic nervous system and the RAAS. The overfill theory, on the other hand, implicates primary renal sodium and water retention that translates into elevated total plasma volume, hypertension, and suppressed RAAS. Distinguishing between the two situations is important because it influences the approach to the use of diuretics in nephrotic patients.

The following observations support the underfill theory for edema formation. Plasma volume, systemic arterial blood pressure, and cardiac output are diminished in some nephrotic patients, especially in children with minimal change disease (see Chapter 17), and can be corrected by plasma volume expansion with albumin infusion. The Starling forces governing the fluid movement across the capillary wall equal the difference of the hydrostatic pressure and the oncotic pressures gradients. The gradual fall in the plasma albumin concentration and the plasma oncotic pressure is mitigated by the reduced entry of albumin into the interstitial space and a concurrent decline in interstitial oncotic pressure. Consequently, less ECF volume expansion and edema formation is noted unless hypoalbuminemia is very severe.²⁸ Thus, nephrotic patients who are underfilled and are predisposed to acute kidney injury despite generalized edema generally have serum albumin concentrations less than 2 g/dl (20 g/l).

Observations supporting the overfill theory include studies of adults with minimal change disease (MCD) who have increased blood volume and blood pressure. After prednisone-induced remission, there are reductions in plasma volume and blood pressure decline with an increase in plasma renin activity. However, evaluation of intravascular volume is somewhat unreliable because the afferent stimulus for edema formation appears to be a dynamic process giving different results when measurements are taken at different phases of edema formation.²⁸ Other findings supporting primary renal sodium retention are studies in experimental animals with unilateral nephrotic syndrome, which demonstrate that sodium retention occurs secondary to increased reabsorption in the collecting tubules.²⁹ It has been shown in experimental animals that increased abundance and apical targeting of epithelial sodium channel (ENaC) subunits in the connecting tubule and collecting duct play an important role in the pathogenesis of sodium retention in nephrotic syndrome.³⁰

In summary, nephrotic patients with arterial underfilling are more likely to have MCD with severe hypoalbuminemia, preserved GFR, and low blood pressure or postural hypotension. Other glomerular diseases are more often associated with an overfill picture with volume expansion, raised blood pressure, and a decline in GFR. It has been postulated that interstitial inflammatory cells, a feature of some glomerular diseases other than MCD, may facilitate an increase in sodium retention and hypertension by releasing mediators that cause vasoconstriction.³¹

Drug-Induced Edema

Ingestion of several types of drugs may generate peripheral edema. Systemic vasodilators such as minoxidil and diazoxide induce arterial underfilling and subsequent sodium with water retention, through mechanisms similar to those in CHF or cirrhosis. Dihydropyridine calcium channel blockers may cause peripheral edema, which is related to redistribution of fluid from the vascular space into the interstitium, possibly induced by

capillary afferent sphincteric vasodilation in the absence of an appropriate microcirculatory myogenic reflex. This facilitates transmission of the systemic pressure to the capillary circulation.³² Fluid retention and CHF exacerbation may be seen with thiazolidinediones, used for the treatment of type 2 diabetes mellitus; the mechanism involves activation of peroxisome proliferator-activated receptor γ (PPAR γ) that leads to stimulation of sodium reabsorption by the sodium channels in collecting tubule cells.³³ NSAIDs can exacerbate volume expansion in CHF and cirrhotic patients by decreasing vasodilatory prostaglandins in the afferent arteriole of the glomerulus.

Idiopathic Edema

Idiopathic edema is an ill-defined syndrome characterized by intermittent edema secondary to sodium and water retention most frequently noted on the upright position. Patients often complain of face and hand edema, leg swelling, and variable weight gain.³⁴ It occurs most often in menstruating women. Concomitant misuse of diuretics or laxatives is also common in patients with this disorder, which may chronically stimulate the RAAS. The diagnosis is usually made by exclusion of other causes of edema after history, physical examination, and investigation.

Sodium and Water Retention in Pregnancy

In the first trimester of normal pregnancy, systemic arterial vasodilation and a decrease in blood pressure occur in association with a compensatory increase in cardiac output.³⁵ After this state of arterial underfilling, activation of the RAAS with resultant renal sodium and water retention occurs early in normal pregnancy. A decrease in plasma osmolality, stimulation of thirst, and persistent nonosmotic vasopressin release are other features of normal pregnancy. In contrast to disease states such as CHF and cirrhosis, pregnancy is associated with an increase in GFR and renal blood flow. The increased GFR, leading to higher filtered load and increased distal sodium delivery in pregnancy, no doubt contributes to the better escape from the sodium-retaining effect of aldosterone compared with CHF patients. This attenuates edema formation compared with other edematous disorders. The cause of peripheral vasodilation in pregnancy, however, is multifactorial. Estrogen upregulates endothelial nitric oxide synthase in pregnancy, and inhibitors of nitric oxide synthesis normalize the systemic and renal hemodynamics in rat pregnancy.³⁶ The placenta creates an arteriovenous fistula in the maternal circulation, which contributes to systemic vasodilation. High levels of vasodilating prostaglandins are another contributing factor.³⁷ Relaxin, which rises early in gestation, can also contribute to the circulatory changes in the kidney and other maternal organs during pregnancy.³⁸

Clinical Manifestations

A thorough history and physical examination are important to identify the etiology of ECF volume expansion and edema. A known history of an underlying disease, such as coronary artery disease, hypertension, or liver cirrhosis, can pinpoint the underlying mechanism of edema formation. Patients with left-sided heart failure may present with exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea; patients with right-sided heart failure or biventricular failure may exhibit weight gain and lower limb swelling. Physical examination reveals JVP elevation, pulmonary crackles, a third heart sound, or dependent peripheral edema that may be elicited in the ankles or sacrum.

Nephrotic patients classically present with periorbital edema because of their ability to lie flat during sleep. However, severe cases may exhibit marked generalized edema with anasarca. Cirrhotic patients present with ascites and lower limb edema consequent to portal hypertension and hypoalbuminemia. Physical examination may reveal stigmata of chronic liver disease and splenomegaly.

Diagnostic and Therapeutic Approach

Management of ECF volume expansion consists of recognizing and treating the underlying cause and attempting to achieve negative sodium balance by dietary sodium restriction and administration of diuretics. Before embarking on diuretic therapy in a congested patient, it is imperative to appreciate that ECF volume expansion may have occurred as a compensatory mechanism for arterial underfilling (e.g., in CHF and cirrhosis). Therefore, a judicious approach is necessary to avoid a precipitous fall in cardiac output and tissue perfusion. Rapid removal of excess fluid is generally necessary only in life-threatening situations, such as pulmonary edema and hypervolemia-induced hypertension, whereas a more gradual approach is warranted in less compromised patients.

Moderate dietary sodium restriction (2 to 3 g/day; 86 to 130 mmol/day) should be encouraged. If salt substitutes are used, it is important to consider that they contain potassium chloride, and therefore they should not be used for patients with advanced renal impairment or those who are concurrently taking potassium-sparing diuretics. Restriction of total fluid intake is usually necessary only for hyponatremic patients. Careful inquiry about concomitant medications that promote sodium restriction, such as NSAIDs, should be carried out, and they should be discontinued. Diuretics are the cornerstone of therapy to remove excess volume (see later discussion). Other measures can be employed when there is inadequate or lack of response to diuretics. In the case of liver cirrhosis, large-volume paracentesis with albumin infusion can be employed to remove large volumes of ascitic fluid. Interventional maneuvers to shunt ascitic fluid to a central vein can also be considered in refractory ascites, and they may result in improvement of the GFR and sodium excretion. Extracorporeal fluid removal by ultrafiltration can be used in patients with acute decompensated heart failure accompanied by renal insufficiency or diuretic resistance. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are adjunctive disease-modifying agents in cases of CHF and nephrotic syndrome. Additional aggressive therapies for cardiac failure include antiarrhythmic agents, positive inotropes, and mechanical assist devices such as intra-aortic balloon pump.

The treatment of suspected diuretic-induced edema, which is associated with persistent secondary hyperaldosteronism, is to withdraw diuretics for 3 to 4 weeks after warning the patient that edema may worsen initially. If the edema does not improve after 4 weeks, spironolactone can be instituted at a dose of 50 to 100 mg daily and increased to a maximum of 400 mg daily.

Diuretics

Principles of Action

Diuretics are the mainstay of therapy for edematous states. Diuretics can be classified into five classes on the basis of their predominant sites of action along the nephron (Fig. 7.10). As a group, most diuretics reach their luminal transport sites through tubular fluid secretion. All but osmotic agents have a high degree

of protein binding, which limits glomerular filtration, traps them in the vascular spaces, and allows them to be delivered to the proximal convoluted tubule for secretion.³⁹ They act by inhibiting sodium reabsorption with an accompanying anion that is usually chloride. The resultant natriuresis decreases the ECF. In spite of the fact that administration of a diuretic causes a sustained net deficit in total body sodium, the time course of natriuresis is limited because renal mechanisms attenuate the sodium excretion. This phenomenon is known as diuretic braking, and its mechanism includes activation of the sympathetic nervous and RAAS systems, decreased systemic and renal arterial blood pressure, hypertrophy of the distal nephron cells with increased expression of epithelial transporters, and perhaps alterations in natriuretic hormones such as ANP.⁴¹

Adverse Effects

Many of the commonly used diuretics are derived from sulfanilamide and may therefore induce allergy in susceptible patients manifested as hypersensitivity reactions, usually as a rash or rarely acute interstitial nephritis. The most serious adverse effects of diuretics are electrolyte disturbances. By blocking sodium reabsorption in the loop of Henle and the distal tubule, loop and thiazide diuretics cause natriuresis and increased distal sodium delivery. The resultant negative sodium balance activates the RAAS. The effect of aldosterone to enhance distal potassium and hydrogen excretion can lead to hypokalemia and metabolic alkalosis. Patients should therefore be monitored, and oral supplementation or addition of a potassium-sparing diuretic may need to be considered. Loop diuretics impair tubular reabsorption by abolishing the transepithelial potential gradient and thus increase excretion of magnesium and calcium. Thiazide diuretics exert the same effect on magnesium, but contrary to loop diuretics, they decrease urinary calcium losses and are therefore preferred in the treatment of hypercalciuric states and in subjects with osteoporosis. Thiazide diuretics interfere with urine diluting mechanisms by blocking sodium reabsorption at the distal convoluted tubule, an effect that may pose a risk of hyponatremia. Acutely, loop and thiazide diuretics increase the excretion of uric acid, whereas chronic administration results in reduced uric acid excretion. The chronic effect may be due to enhanced transport in the proximal convoluted tubule secondary to volume depletion, leading to increased uric acid reabsorption, or competition between the diuretic and uric acid for secretion in the proximal tubule, leading to reduced uric acid secretion. Other adverse effects that may occur with large doses include ototoxicity with loop diuretics, particularly when an aminoglycoside is coadministered, and gynecomastia that may develop with spironolactone.

Diuretic Tolerance and Resistance

Long-term loop diuretic tolerance refers to the resistance of their action as a consequence of distal nephron segment hypertrophy and enhanced sodium reabsorption that follows increased exposure to solutes not absorbed proximally.³⁹ This problem can be addressed by combining loop and thiazide diuretics as the latter block those responsible distal nephron sites. Diuretic resistance refers to edema that is or has become refractory to a given diuretic. An algorithm for diuretic therapy in patients with edema caused by renal, hepatic, or cardiac disease is outlined in Figure 7.11. Diuretic resistance can be due to several causes. Chronic kidney disease is associated with a decreased tubular delivery and secretion of diuretics, which subsequently reduces their concentration at the active site in the tubular lumen. In

Figure 7.10 Tubule transport systems and sites of action of diuretics. (Modified from reference 40.)

nephrotic syndrome, it was once thought that the high protein content of tubular fluid increases protein binding of furosemide and other loop diuretics and therefore inhibits their action. However, recent data suggest that urinary protein binding does not affect the response to furosemide.⁴² As explained earlier, arterial underfilling that takes place in cirrhosis and CHF is associated with diminished nephron responsiveness to diuretics because of increased proximal tubular sodium reabsorption, leading to decreased delivery of sodium to the distal nephron segment sites of diuretic action. NSAIDs block prostaglandin-mediated increases in renal blood flow and increase the expression of the sodium-potassium-chloride cotransporters in the thick ascending limb.

Salt restriction is the key approach to lessening postdiuretic sodium retention. Further approaches to antagonize diuretic resistance include increasing the dose of loop diuretic, administering more frequent doses, and using combination therapy to sequentially block more than one site in the nephron as that may result in a synergistic interaction between diuretics. Highly resistant edematous patients may be treated with ultrafiltration.

Loop Diuretics

This group includes furosemide, bumetanide, torsemide, and ethacrynic acid. They act by blocking the sodium-potassium-chloride cotransporters at the apical surface of the thick ascending limb cells, thereby diminishing net reabsorption. Loop diuretics are the most potent of all diuretics because of a

combination of two factors. They are able to inhibit the reabsorption of 25% of filtered sodium that normally takes place at the thick ascending limb of the loop of Henle. Moreover, the nephron segment past the thick ascending limb does not possess the capacity to reabsorb completely the volume of fluid exiting the thick ascending limb. The oral bioavailability of furosemide varies between 10% and 100%; that of bumetanide and torsemide is comparatively higher. As a class, loop diuretics have short elimination half-lives, and consequently the dosing interval needs to be short to maintain adequate levels in the lumen. Excessive prolongation of dosing interval may lead to avoid sodium reabsorption by the nephron, which may result in post-diuretic sodium retention.

The intrinsic potency of a diuretic is defined by its dose-response curve, which is generally sigmoid. The steep dose-response is the reason that loop diuretics are often referred to as threshold drugs. This is exemplified by furosemide, which can initiate diuresis in a subject with normal renal function with an intravenous dose of 10 mg, and a maximal effect is seen with 40 mg. Above this dose, little or no extra benefit occurs and side effects may increase. Furthermore, the effective diuretic dose is higher in patients with CHF, advanced cirrhosis, and renal failure (Fig. 7.12). In patients who have poor responses to intermittent doses of a loop diuretic, a continuous intravenous infusion can be tried; this enhances the response by virtue of maintaining an effective amount of the drug at the site of action.⁴³ The benefit of continuous infusion, however, was not confirmed

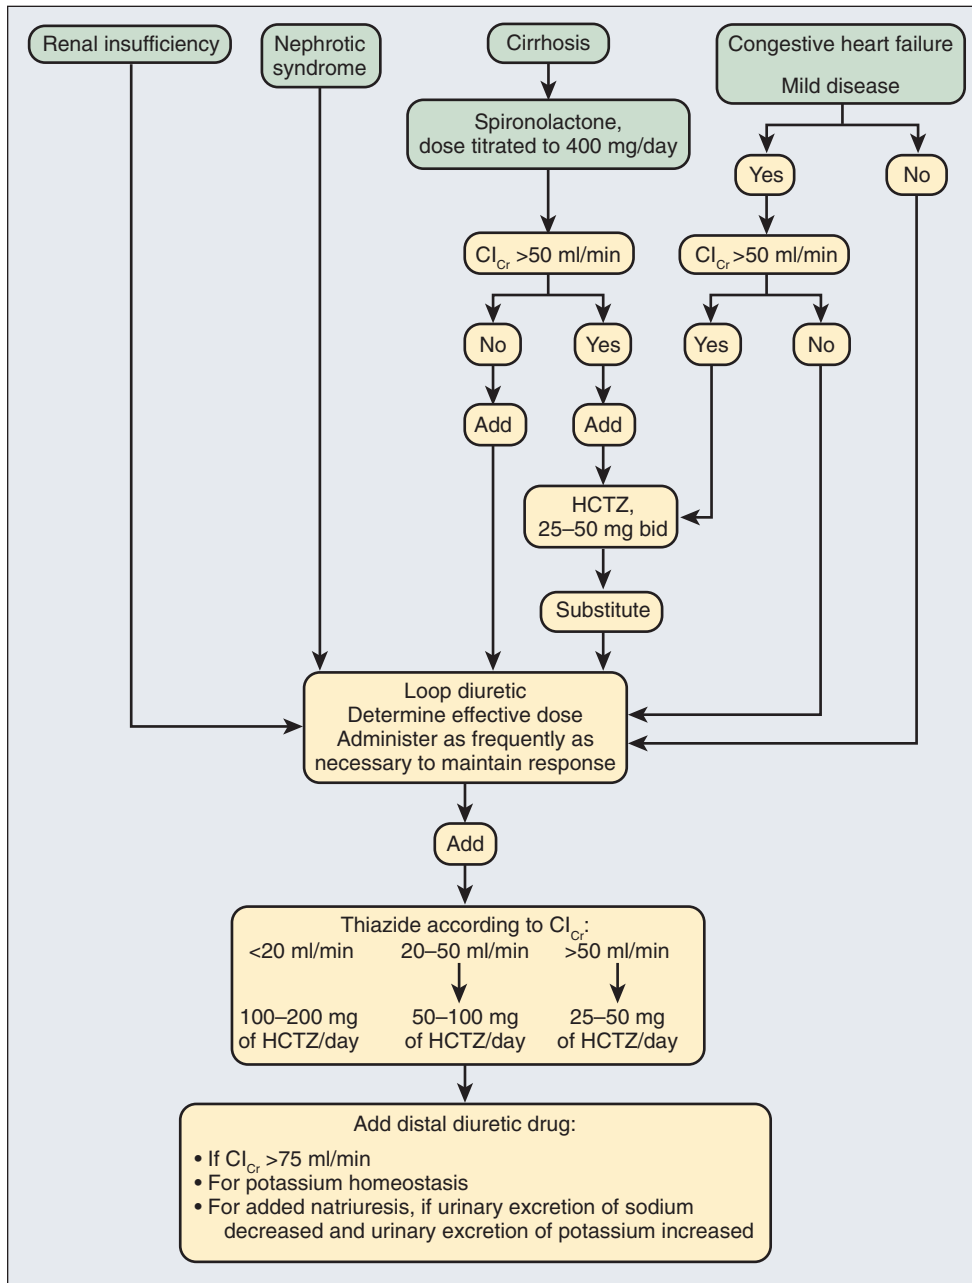

Figure 7.11 Algorithm for diuretic therapy in patients with edema caused by renal, hepatic, or cardiac disease. HCTZ, hydrochlorothiazide. (Modified with permission from reference 39.)

	Renal Insufficiency				Preserved Renal Function					
	Moderate		Severe		Nephrotic Syndrome		Cirrhosis		Congestive Heart Failure	
	PO	IV	PO	IV	PO	IV	PO	IV	PO	IV
Furosemide	80–160	80	240	200	240	120	80–160	40–80	160–240	40–80
Bumetanide	2–3	2–3	8–10	8–10	3	3	1–2	1	2–3	2–3
Torsemide	50	50	100	100	50	50	10–20	10–20	50	20–50

Figure 7.12 Therapeutic regimens for loop diuretics. (Modified from reference 45.)

in a Cochrane review, which concluded that available data are insufficient to confidently assess the merits of each approach (bolus or continuous) despite greater diuresis and a better safety profile of the continuous infusion.⁴⁴ Ethacrynic acid has typical pharmacologic characteristics of other loop diuretics, but its ototoxic potential is greater, and it is therefore reserved for patients allergic to other loop diuretics.

Distal Convoluted Tubule Diuretics

This group includes thiazide diuretics such as chlorothiazide, hydrochlorothiazide, and chlorthalidone in addition to metolazone and indapamide. They inhibit sodium chloride absorption in the distal tubule, where up to 5% of filtered sodium and chloride is reabsorbed, and are therefore less potent than loop diuretics. Thiazides have relatively long half-lives and can be administered once or twice per day. Metolazone is an agent with pharmacologic characteristics similar to those of thiazide diuretics. It is more commonly used in conjunction with other classes of diuretics. It has a longer elimination half-life (about 2 days); therefore, more rapidly acting and predictable thiazide agents may be preferred.

Thiazides may be used alone to induce diuresis in patients with mild CHF but more commonly in combination to synergize the effect of loop diuretics by blocking multiple nephron segment sites. Because thiazide diuretics must reach the lumen to be effective, higher doses are required in patients with impaired renal function. Thiazides (possibly excluding metolazone and indapamide) are ineffective in patients with advanced renal impairment (GFR is less than 30 to 40 ml/min). In these patients, thiazides can enhance the diuretic effect of loop diuretics if they are coadministered in sufficient doses to attain effective nephron lumen concentration. If it is used, such combination therapy should be initiated under close monitoring because of a pronounced risk of hypokalemia and excessive ECF depletion.

Collecting Duct Diuretics

Amiloride, triamterene, and the aldosterone antagonists spironolactone and eplerenone act on the collecting duct. Amiloride and triamterene act primarily in the cortical collecting tubule or the connecting tubule and cortical collecting duct by interfering with sodium reabsorption through the apical epithelial sodium channels (ENaC). They inhibit potassium secretion indirectly by dissipating the electronegative gradient normally created by sodium reabsorption that favors potassium secretion. Spironolactone and eplerenone are competitive antagonists of aldosterone and cause natriuresis and potassium retention. Potassium-sparing diuretics are considered to be weak diuretics because they block only a small part (about 3%) of the filtered sodium load reaching their site of action. Hence, they are most commonly used in combination with other diuretics to augment diuresis or to preserve potassium. Nevertheless, careful monitoring is essential if combinations therapy is employed to prevent dangerous hyperkalemia. Most vulnerable patients include those with underlying renal dysfunction, those with CHF, diabetic patients, and those concurrently taking ACE inhibitors, ARBs, NSAIDs, and β -blockers. Collecting duct diuretics are considered first-line agents in certain conditions, for example, spironolactone in liver cirrhosis with ascites and amiloride in the treatment of Liddle syndrome.

Proximal Tubule Diuretics

Acetazolamide is the prototype and acts by blocking the activity of the sodium-hydrogen ion exchanger, thus increasing sodium

bicarbonate excretion. These diuretics are weak because proximal sodium reabsorption is mediated by other pathways and also because the loop of Henle has a large reabsorptive capacity that captures most of the sodium and chloride escaping from the proximal tubule. Acetazolamide generates a hyperchloremic metabolic acidosis particularly with prolonged use. It may also cause hypokalemia because of increased distal sodium delivery; it may cause hypophosphatemia, but the mechanism of this is not well understood. Rarely used as a single agent, this diuretic is most commonly used in combination with other diuretics, in the treatment of metabolic alkalosis accompanied by edematous states, and in chronic obstructive pulmonary disease (COPD).

Osmotic Diuretics

Osmotic diuretics are substances that are freely filtered at the glomerulus but are poorly reabsorbed. Mannitol is the prototype of these diuretics. The mechanism by which mannitol produces diuresis is that it increases the osmotic pressure within the lumen of the proximal tubule and the loop of Henle. This causes enhanced water diuresis and, to a lesser extent, sodium and potassium excretion.⁴⁶ Patients with reduced cardiac output may develop pulmonary edema when given mannitol because of an initial intravascular hypertonic phase. Therefore, mannitol is not a preferred agent for treatment of edematous states but is rather used to treat cerebral edema induced by trauma or neoplasms and to reduce intraocular pressure. Another use for mannitol is in the treatment of dialysis disequilibrium syndrome, whereby it increases the serum osmolality and hence decreases the rapid rate of solute removal by dialysis, which is thought to be responsible for the symptoms of the syndrome.

Disorders of Water Metabolism

Chirag Parikh, Tomas Berl

PHYSIOLOGY OF WATER BALANCE

The maintenance of the tonicity of body fluids within a narrow physiologic range is made possible by homeostatic mechanisms that control the intake and excretion of water. Vasopressin (also known as arginine vasopressin [AVP] or antidiuretic hormone [ADH]) governs the excretion of water by its effect on the renal collecting system. Osmoreceptors located in the hypothalamus control the secretion of vasopressin in response to changes in tonicity.

In the steady state, water intake matches water losses. Water intake is regulated by the need to maintain a physiologic serum osmolality of 285 to 290 mOsm/kg. Despite major fluctuations of solute and water intake, the total solute concentration (i.e., the tonicity) of body fluids is maintained virtually constant. The ability to dilute and to concentrate the urine allows a wide flexibility in urine flow (see Chapter 2). During water loading, the diluting mechanisms permit excretion of 20 to 25 liters of urine per day, and during water deprivation, the urine volume may be as low as 0.5 liter per day.^{1,3}

VASOPRESSIN

Vasopressin plays a critical role in determining the concentration of urine. It is a cyclic peptide (1099 d) and is synthesized and secreted by the specialized supraoptic and paraventricular magnocellular nuclei in the hypothalamus. Vasopressin has a short half-life of about 15 to 20 minutes and is rapidly metabolized in the liver and the kidney.

Osmotic Stimuli for Vasopressin Release

Substances that are restricted to the extracellular fluid (ECF), such as hypertonic saline and mannitol, decrease cell volume by acting as effective osmoles and enhancing osmotic water movement from the cell. This stimulates vasopressin release; in contrast, urea and glucose cross cell membranes and do not cause any change in cell volume. The “osmoreceptor” cells, located close to the supraoptic nuclei in the anterior hypothalamus, are sensitive to changes in plasma osmolality as small as 1%. In humans, the osmotic threshold for vasopressin release is 280 to 290 mOsm/kg (Fig. 8.1). This system is so efficient that plasma osmolality usually does not vary by more than 1% to 2% despite wide fluctuations in water intake.

Nonosmotic Stimuli for Vasopressin Release

There are several other nonosmotic stimuli for vasopressin secretion. Decreased effective circulating volume (e.g., heart

failure, cirrhosis, vomiting) causes discharge from parasympathetic afferent nerves in the carotid sinus baroreceptors and increases vasopressin secretion. Other nonosmotic stimuli include nausea, postoperative pain, and pregnancy. Much higher vasopressin levels can be achieved with hypovolemia than with hyperosmolality, although a large (7%) decrease in blood volume is required before this response is initiated.

Mechanism of Vasopressin Action

Vasopressin binds three types of receptors coupled to G proteins: the V_{1a} (vascular and hepatic), V_{1b} (anterior pituitary), and V_2 receptors. The V_2 receptor is primarily localized in the collecting duct and leads to an increase in water permeability (Fig. 8.2) through aquaporin 2 (AQP2), which is a member of a family of cellular water transporters.⁴ AQP1 is localized in the apical and basolateral region of the proximal tubule epithelial cells and the descending limb of Henle and accounts for the high water permeability of these nephron segments. Because AQP1 is constitutively expressed, it is not subject to regulation by vasopressin. In contrast, AQP2 is found exclusively in apical plasma membranes and intracellular vesicles in the collecting duct principal cells. Vasopressin affects both the short- and long-term regulation of AQP2. The short-term regulation, also described as the shuttle hypothesis, explains the rapid and reversible increase (within minutes) in collecting duct water permeability that follows vasopressin administration. This involves the insertion of water channels from subapical vesicles into the luminal membrane. Long-term regulation involves vasopressin-mediated increased transcription of genes involved in AQP2 production and occurs if circulating vasopressin levels are elevated for 24 hours or more. The maximal water permeability of the collecting duct epithelium is increased as a consequence of an increase in the total number of AQP2 channels per cell. This process is not readily reversible.

AQP3 and AQP4 are located on the basolateral membranes of the collecting duct (see Fig. 8.2) and are probably involved in water exit from the cell. AQP3 is also urea permeable and under the stimulus of vasopressin increases the permeability of the collecting duct to urea, resulting in its movement into the interstitium. AQP4 is also in the hypothalamus and is a candidate osmoreceptor for the control of vasopressin release.

THIRST AND WATER BALANCE

Hypertonicity is the most potent stimulus for thirst, with a change of only 2% to 3% in plasma osmolality producing a strong desire to drink water. The osmotic threshold for thirst usually occurs at 290 to 295 mOsm/kg H_2O and is above the

threshold for vasopressin release (see Fig. 8.1). It closely approximates the level at which maximal concentration of urine is achieved. Hypovolemia, hypotension, and angiotensin II (ANG II) are also stimuli for thirst. Between the limits imposed by the osmotic thresholds for thirst and vasopressin release, plasma osmolality may be regulated more precisely by small, osmoregulated adjustments in urine flow and water intake. The exact level at which balance occurs depends on various factors, for example, insensible losses through skin and lungs, the gains incurred from

drinking water and eating, and water generated from metabolism. In general, overall intake and output come into balance at a plasma osmolality of 288 mOsm/kg.

QUANTITATION OF RENAL WATER EXCRETION

Urine volume can be considered as having two components. The osmolar clearance (C_{osm}) is the volume needed to excrete solutes at the concentration of solutes in plasma. The free water clearance (C_{water}) is the volume of water that has been added to (positive C_{water}) or subtracted from (negative C_{water}) isotonic urine (C_{osm}) to create either hypotonic or hypertonic urine.

Urine volume flow (V) comprises the isotonic portion of urine (C_{osm}) plus the free water clearance (C_{water}).

$$V = C_{\text{osm}} + C_{\text{water}}$$

and, therefore,

$$C_{\text{water}} = V - C_{\text{osm}}$$

The term C_{osm} relates urine osmolality to plasma osmolality P_{osm} by

$$C_{\text{osm}} = \left(\frac{U_{\text{osm}} \times V}{P_{\text{osm}}} \right)$$

Therefore,

$$\begin{aligned} C_{\text{water}} &= V - \left(\frac{U_{\text{osm}} \times V}{P_{\text{osm}}} \right) \\ &= V \left(1 - \frac{U_{\text{osm}}}{P_{\text{osm}}} \right) \end{aligned}$$

Figure 8.1 Mechanisms maintaining plasma osmolality. The response of thirst, vasopressin levels, and urinary osmolality to changes in serum osmolality. (Modified from reference 2.)

Figure 8.2 Cellular mechanism of vasopressin action. Vasopressin binds to V_2 receptors on the basolateral membrane and activates G proteins that initiate a cascade resulting in aquaporin 2 (AQP2) insertion in the luminal membrane. This then allows water uptake into the cell. ATP, adenosine triphosphate; AVP, arginine vasopressin; cAMP, cyclic adenosine monophosphate; PKA, protein kinase A; VAMP2, vesicle-associated membrane protein 2. (Modified from reference 3.)

This relationship determines that

1. in hypotonic urine ($U_{\text{osm}} < P_{\text{osm}}$), C_{water} is positive;
2. in isotonic urine ($U_{\text{osm}} = P_{\text{osm}}$), C_{water} is zero;
3. in hypertonic urine ($U_{\text{osm}} > P_{\text{osm}}$), C_{water} is negative (i.e., water is retained).

If excretion of free water in a polyuric patient is unaccompanied by water intake, the patient will become hypernatremic. Conversely, failure to excrete free water with increased water intake can cause hyponatremia.

A limitation of the equation is that it fails to predict clinically important alterations in plasma tonicity and serum Na^+ concentration because it factors in urea. Urea is an important component of urinary osmolality; however, because it crosses cell membranes readily, it does not establish a transcellular osmotic gradient and does not cause water movement between fluid compartments. Therefore, it does not influence serum Na^+ concentration or the release of vasopressin. As a result, changes in serum Na^+ concentration are better predicted by electrolyte free water clearance [$C_{\text{water}}(e)$]. The equation can be modified, replacing P_{osm} by plasma Na^+ concentration (P_{Na}) and the urine osmolality by urinary sodium and potassium concentrations ($U_{\text{Na}} + U_{\text{K}}$):

$$C_{\text{water}}(e) = V \left(1 - \frac{U_{\text{Na}} + U_{\text{K}}}{P_{\text{Na}}} \right)$$

If $U_{\text{Na}} + U_{\text{K}}$ is less than P_{Na} , then $C_{\text{water}}(e)$ is positive and the serum Na^+ concentration increases. If $U_{\text{Na}} + U_{\text{K}}$ is greater than P_{Na} , then $C_{\text{water}}(e)$ is negative and serum Na^+ concentration decreases. In the clinical setting, it is more appropriate to use the equation for electrolyte free clearance to predict if a patient's serum Na^+ concentration will increase or decrease in the face of the prevailing water excretion. For example, in a patient with high urea excretion, the original equation would predict negative water excretion and a decrease in serum Na^+ concentration; but in fact, serum Na^+ concentration increases, which is accurately predicted by the latter equation.

SERUM SODIUM CONCENTRATION, OSMOLALITY, AND TONICITY

The countercurrent mechanism of the kidneys, which allows urinary concentration and dilution, acts in concert with the hypothalamic osmoreceptors through vasopressin secretion to keep serum $[\text{Na}^+]$ and tonicity within a very narrow range (Fig. 8.3). A defect in the urine-diluting capacity coupled with excess water intake leads to hyponatremia. A defect in urinary concentrating ability with inadequate water intake leads to hypernatremia.

Serum $[\text{Na}^+]$ along with its accompanying anions accounts for nearly all the osmotic activity of the plasma. Calculated serum osmolality is given by $2[\text{Na}^+] + \text{BUN (mg/dl)}/2.8 + \text{glucose (mg/dl)}/18$, where BUN is blood urea nitrogen. The addition of other solutes to ECF results in an increase in measured osmolality (Fig. 8.4). Solute that are permeable across cell membranes do not cause water movement and do cause hypertonicity without causing cellular dehydration, for example, in uremia or ethanol intoxication. By comparison, a patient with diabetic ketoacidosis has an increase in plasma glucose, which cannot move freely across cell membranes in the absence of insulin and therefore causes water to move from the cells to the ECF, leading to cellular dehydration and lowering serum $[\text{Na}^+]$. This can be viewed as “translocational” at the cellular level, as the serum $[\text{Na}^+]$ does

Methanol	

Figure 8.4 Effects of osmotically active substances on serum sodium levels.

not reflect change in total body water but rather reflects a movement of water from intracellular to extracellular space. A correction whereby a decrease in serum $[\text{Na}^+]$ of 1.6 mmol/l for every 100 mg/dl (5.6 mmol/l) of glucose used may somewhat underestimate the impact of glucose to decrease serum sodium concentration.

Pseudohyponatremia occurs when the solid phase of plasma (usually 6% to 8%) is increased by large increments in either lipids or proteins (e.g., in hypertriglyceridemia and paraproteinemias). Serum osmolality is normal in pseudohyponatremia. This false result occurs because the usual method that measures the concentration of sodium uses whole plasma and not just the liquid phase, in which the concentration of sodium is 150 mmol/l. Many laboratories are now moving to direct ion-selective potentiometry, which will give the true aqueous sodium activity. In the absence of a direct-reading potentiometer, an estimate of plasma water can be obtained from the well-validated formula⁶

Figure 8.5 Mechanisms of urine dilution. Normal determinants of urinary dilution and disorders causing hyponatremia. (Modified from reference 7.)

$$\text{Plasma water content (\%)} = 99.1 - (0.1 \times L) - (0.07 \times P)$$

where L and P refer to the total lipid and protein concentration (in g/l), respectively. For example, if the formula reveals that plasma water is 90% of the plasma sample rather than the normal 93% (which yields a serum sodium concentration of 140 mmol/l as $150 \times 0.93 = 140$), the concentration of measured sodium would be expected to decrease to 135 mmol/l (150×0.90).

ESTIMATION OF TOTAL BODY WATER

In the normal man, total body water is approximately 60% of body weight (50% in women and obese individuals). With hyponatremia or hypernatremia, the change in total body water can be calculated from the serum Na^+ concentration by the following formula:

$$\text{Water excess} = 0.6W \times \left(1 - \frac{[\text{Na}^+]_{\text{obs}}}{140} \right)$$

$$\text{Water deficit} = 0.6W \times \left(\frac{[\text{Na}^+]_{\text{obs}}}{140} - 1 \right)$$

where $[\text{Na}^+]_{\text{obs}}$ is observed sodium concentration (in mmol/l) and W is body weight (in kilograms). By use of this formula, a change

of 10 mmol/l in the serum $[\text{Na}^+]$ in a 70-kg individual is equivalent to a change of 3 liters in free water.

HYPONATREMIC DISORDERS

Hyponatremia is defined as serum $[\text{Na}^+]$ of less than 135 mmol/l and equates with a low serum osmolality once translocational hyponatremia and pseudohyponatremia are ruled out. True hyponatremia develops when normal urinary dilution mechanisms (Fig. 8.5) are disturbed. This may occur by three mechanisms. First, hyponatremia may result from intrarenal factors, such as a diminished glomerular filtration rate (GFR) and an increase in proximal tubular fluid and Na^+ reabsorption, which decrease distal delivery to the diluting segments of the nephron. Hyponatremia may also result from a defect in $\text{Na}^+\text{-Cl}^-$ transport out of the water-impermeable segments of the nephrons (the thick ascending limb of Henle [TALH] or distal convoluted tubule). Most commonly, hyponatremia results from continued stimulation of vasopressin secretion by nonosmotic mechanisms despite the presence of serum hypo-osmolality.

Etiology and Classification of Hyponatremia

Once pseudohyponatremia and translocational hyponatremia are ruled out and the patient is established as truly hypo-osmolar, the next step is to classify the patient as hypovolemic, euvolemic, or hypervolemic (Fig. 8.6).

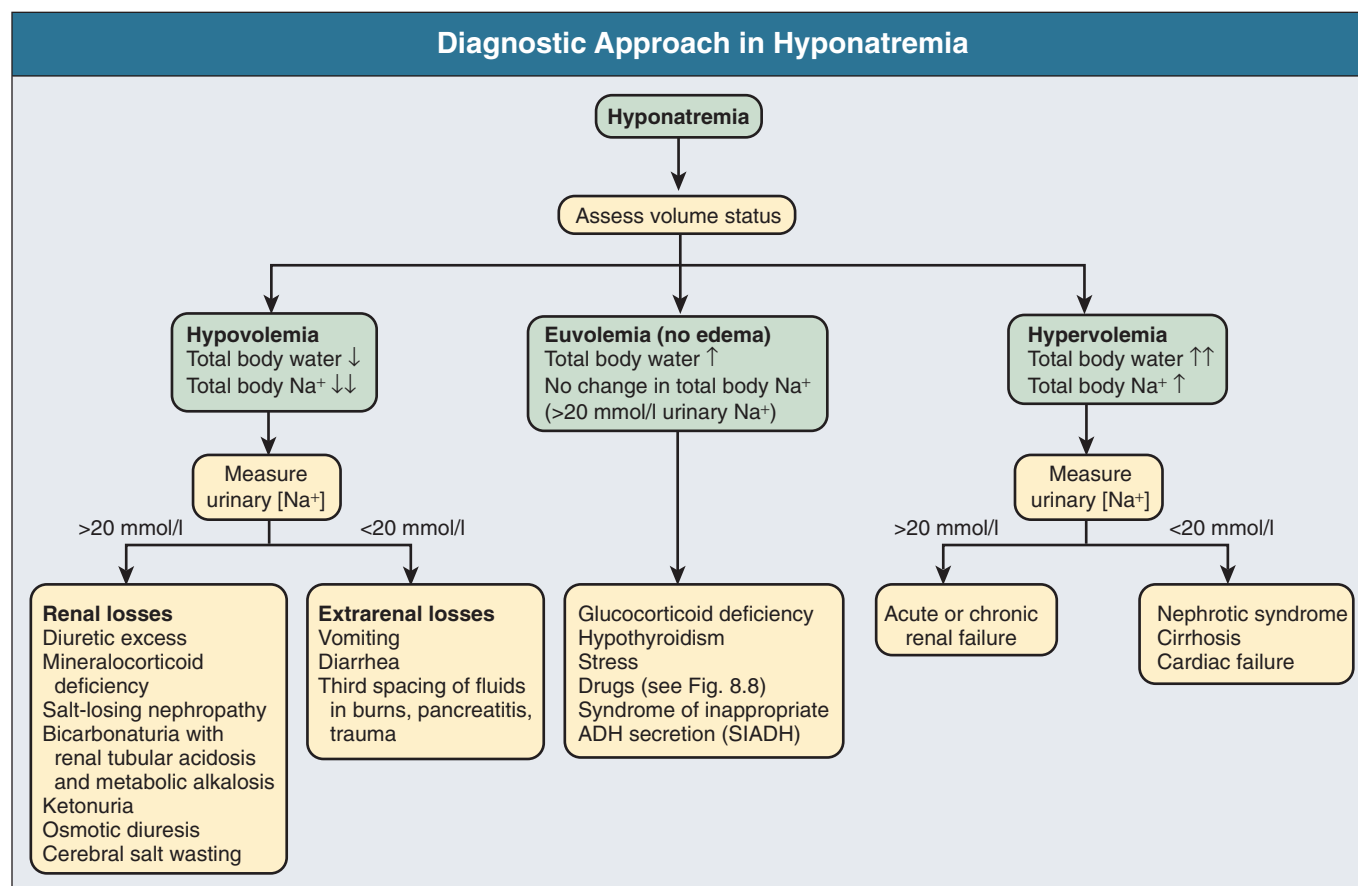

Figure 8.6 Diagnostic approach for the patient with hyponatremia. (Modified with permission from reference 5.)

Hypovolemia: Hyponatremia Associated with Decreased Total Body Sodium

A patient with hypovolemic hyponatremia has both a total body Na^+ and a water deficit, with the Na^+ deficit exceeding the water deficit. This occurs in patients with high gastrointestinal and renal losses of water and solute accompanied by free water or hypotonic fluid intake. The underlying mechanism is the non-osmotic release of vasopressin stimulated by volume contraction, which maintains vasopressin secretion despite the hypotonic state. Measurement of urinary Na^+ concentration is a useful tool in helping to diagnose these conditions (see Fig. 8.6).

Gastrointestinal and Third-Space Sequestered Losses In the setting of diarrhea or vomiting, the kidney responds to volume contraction by conserving Na^+ and Cl^- . A similar pattern is observed in burn patients and in patients with sequestration of fluids in third spaces, as in the peritoneal cavity with peritonitis or pancreatitis or in the bowel lumen with ileus. In all these situations, the urinary Na^+ concentration is usually less than 10 mmol/l and the urine is hyperosmolar. An exception to this is in patients with vomiting and metabolic alkalosis. Here, the increased HCO_3^- excretion requires simultaneous cation excretion such that urinary Na^+ concentration may be more than 20 mmol/l despite severe volume depletion and urinary Cl^- less than 10 mmol/l. Likewise, in chronic renal insufficiency, renal salt conservation is impaired and urine Na^+ concentration may be high.

Diuretics Diuretic use is one of the most common causes of hypovolemic hyponatremia associated with a high urine Na^+ concentration. Loop diuretics inhibit Na^+-Cl^- reabsorption in the TALH. This interferes with the generation of a hypertonic medullary interstitium. Therefore, even though volume contraction leads to increased vasopressin secretion, responsiveness to vasopressin is diminished and free water is excreted. In contrast, thiazide diuretics act in the distal tubule by interfering with urinary dilution rather than with urinary concentration, limiting free water excretion. Hyponatremia usually occurs within 14 days of initiation of therapy, although one third of cases present within 5 days. Underweight women and elderly patients appear to be most susceptible. Several mechanisms for diuretic-induced hyponatremia have been postulated, including:

- Hypovolemia-stimulated vasopressin release and decreased fluid delivery to the diluting segment.
- Impaired water excretion through interference with maximal urinary dilution in the cortical diluting segment.
- K^+ depletion, directly stimulating water intake by alterations in osmoreceptor sensitivity and increasing thirst.

Water retention can mask the physical findings of hypovolemia, thereby making the patients with diuretic-induced hyponatremia appear euolemic.

Salt-Losing Nephropathy A salt-losing state sometimes occurs in patients with advanced chronic renal impairment (GFR

<15 ml/min), particularly due to interstitial disease. It is characterized by hyponatremia and hypovolemia. In proximal type 2 renal tubular acidosis, there is renal Na^+ and K^+ wastage despite only moderate renal impairment, and bicarbonaturia obligates urine Na^+ excretion.

Mineralocorticoid Deficiency Mineralocorticoid deficiency is characterized by hyponatremia with ECF volume contraction, urine $[\text{Na}^+]$ above 20 mmol/l, and high serum K^+ , urea, and creatinine. Decreased ECF volume provides the nonosmotic stimulus for vasopressin release.

Osmotic Diuresis An osmotically active, non-reabsorbable solute obligates the renal excretion of Na^+ and results in volume depletion. In the face of continuing water intake, the diabetic patient with severe glycosuria, the patient with a urea diuresis after relief of urinary tract obstruction, and the patient with mannitol diuresis all undergo urinary losses of Na^+ and water leading to hypovolemia and hyponatremia. Urinary $[\text{Na}^+]$ is typically above 20 mmol/l. The ketone bodies β -hydroxybutyrate and acetoacetate also obligate urinary electrolyte losses and aggravate renal Na^+ wasting seen in diabetic ketoacidosis, starvation, and alcoholic ketoacidosis.

Cerebral Salt Wasting Cerebral salt wasting is a syndrome that has been described primarily in patients with subarachnoid hemorrhage. In this condition, the primary defect is salt wasting from the kidneys with subsequent volume contraction, which stimulates vasopressin release. The exact mechanism is not understood, but it is postulated that brain natriuretic peptide increases urine volume and Na^+ excretion. The diagnosis requires evidence of inappropriate sodium losses and reduced effective blood volume. These criteria are rarely fulfilled, suggesting that the entity is overdiagnosed.⁸

Hypervolemia: Hyponatremia Associated with Increased Total Body Sodium

In hypervolemia, if the total body Na^+ is increased more than total body water, there is hyponatremia. This occurs in

congestive heart failure, nephrotic syndrome, and cirrhosis, all of which are associated with impaired water excretion (see Fig. 8.6). These pathophysiologic states are discussed in Chapter 7.

Congestive Heart Failure Edematous patients with heart failure have reduced effective intravascular volume due to lower systemic mean arterial pressure and cardiac output. This reduction is sensed by aortic and carotid baroreceptors activating non-osmotic pathways, and vasopressin is released. In addition, the relative “hypovolemic” state stimulates the renin-angiotensin axis and increases norepinephrine production, which in turn decreases GFR. The decrease in GFR leads to an increase in proximal tubular reabsorption and a decrease in water delivery to the distal tubule.

The neurohumorally mediated decrease in delivery of tubular fluid to the distal nephron and an increase in vasopressin secretion mediate hyponatremia by limiting $\text{Na}^+\text{-Cl}^-$ and water excretion. In addition, low cardiac output and high ANG II levels are potent stimuli of thirst. There is also excessive intracellular targeting of AQP2 to the apical cell membrane of the collecting duct (Fig. 8.7). These effects are most likely a consequence of high circulating levels of vasopressin.

As cardiac function improves with afterload reduction, plasma vasopressin decreases with concomitant improvement in water excretion. The degree of hyponatremia has also been correlated with the severity of cardiac disease and with patient survival; serum Na^+ concentration of less than 125 mmol/l reflects severe heart failure.

Hepatic Failure Patients with cirrhosis and hepatic insufficiency also have increased extracellular volume (i.e., ascites, edema). Because of splanchnic venous dilation, they have an increased plasma volume. Unlike patients with congestive heart failure, cirrhotic patients have an increased cardiac output because of multiple arteriovenous fistulas in their alimentary tract and skin. Vasodilation and arteriovenous fistulas lead to a decrease in mean arterial blood pressure. As the severity of cirrhosis increases, there are progressive increases in plasma renin, norepinephrine, vasopressin, and endothelin. There is also an

Figure 8.7 Changes in aquaporin 2 (AQP2) expression seen in association with different water balance disorders. Levels are expressed as a percentage of control levels (leftmost bar). AQP2 expression is reduced, sometimes dramatically, in a wide range of hereditary and acquired forms of diabetes insipidus (DI) characterized by different degrees of polyuria. Conversely, congestive heart failure and pregnancy are conditions associated with increased expression of AQP2 levels and excessive water retention. (Modified from reference 9.)

associated decline in mean arterial pressure and serum $[Na^+]$. In experimental models of cirrhosis, there is increased expression of vasopressin-regulated AQP2 in collecting ducts.⁴

Nephrotic Syndrome In some patients with nephrotic syndrome, especially children with minimal change disease, hypoalbuminemia and lowered plasma oncotic pressure alter Starling forces, leading to intravascular volume contraction. Most patients with nephrotic syndrome appear to have a renal defect in sodium excretion resulting in increased effective circulating volume. In experimental models of nephrotic syndrome, expression of AQP2 and AQP3 in the renal collecting ducts is downregulated.⁴

Advanced Chronic Renal Impairment Patients with advanced renal impairment, either acute or chronic, have a profound increase in fractional excretion of Na^+ to maintain normal salt balance given the overall decreased number of functioning nephrons. Edema usually develops when the Na^+ ingested exceeds the kidneys' capacity to excrete this load. Likewise, if water intake exceeds threshold, there is positive water balance and hyponatremia. At a GFR of 5 ml/min, only 7.2 liters of filtrate is formed daily. Approximately 30%, or 2.2 liters, of this filtered fluid will reach the diluting segment of the nephron, which is therefore the maximum solute-free water that can be excreted daily.

Euvolemia: Hyponatremia Associated with Normal Total Body Sodium

Euvolemic hyponatremia is the most commonly encountered dysnatremia in hospitalized patients. In these patients, no physical signs of increased total body Na^+ are detected.

Glucocorticoid Deficiency Glucocorticoid deficiency causes impaired water excretion in patients with primary and secondary adrenal insufficiency. Elevation of vasopressin accompanies the water-excretory defect resulting from anterior pituitary and adrenocorticotrophic hormone deficiency. This can be corrected by physiologic doses of corticosteroids. In addition, implicated vasopressin-independent factors are impaired renal hemodynamics and decreased distal fluid delivery to the diluting segments of the nephron.

Hypothyroidism Hyponatremia occurs in patients with severe hypothyroidism, who usually meet the clinical criteria for myxedema coma. A decrease in cardiac output leads to nonosmotic release of vasopressin. A reduction in the GFR leads to diminished free water excretion through decreased distal delivery to the distal nephron. The exact mechanisms are unclear. Although a vasopressin-independent mechanism is suggested by normal suppression of vasopressin after water loading in patients with untreated myxedema, in advanced hypothyroidism, elevated levels of vasopressin in the basal state and after a water load are reported. Hyponatremia is readily reversed by treatment with levothyroxine (thyroxine).

Psychosis Patients with acute psychosis may develop hyponatremia. Some psychogenic drugs are commonly associated with hyponatremia, but psychosis can cause hyponatremia independently. The pathophysiologic process involves an increased thirst perception, a mild defect in osmoregulation that causes vasopressin to be secreted at lower osmolality, and an enhanced renal response to vasopressin. It has been suggested that subjects with self-induced water intoxication may also be more prone to development of rhabdomyolysis.¹⁰

Postoperative Hyponatremia Postoperative hyponatremia mainly occurs as a result of excessive infusion of electrolyte-free water (hypotonic saline or 5% dextrose in water) and the presence of vasopressin, which prevents its excretion. Hyponatremia can also occur despite near-isotonic saline infusion within 24 hours of induction of anesthesia, mostly through the generation of electrolyte-free water by the kidneys in the presence of vasopressin.¹¹ In young women, hyponatremia is rarely accompanied by cerebral edema, leading to seizures and hypoxia with catastrophic neurologic events, particularly after gynecologic surgery. The mechanism has not been fully elucidated, and the patients at highest risk cannot be prospectively identified. Nevertheless, hypotonic fluids should be avoided after surgery, isotonic fluids should be minimized, and serum $[Na^+]$ concentration should be checked if there is any suspicion of hyponatremia (see later discussion).

Exercise-Induced Hyponatremia Hyponatremia is increasingly seen in long-distance runners. A study at a marathon race associated increased risk of hyponatremia with body mass index (BMI) below 20 kg/m², running time exceeding 4 hours, and greatest weight gain.¹² A study in ultramarathon runners showed elevated vasopressin despite normal or low serum sodium concentration.¹³

Drugs Causing Hyponatremia Drug-induced hyponatremia is becoming the most common cause of hyponatremia.¹⁴ Thiazide diuretics are the most common cause, probably followed by selective serotonin reuptake inhibitors (SSRIs). Hyponatremia can be mediated by vasopressin analogues such as desmopressin (brand name DDAVP [1-desamino-D-arginine vasopressin]), drugs that enhance vasopressin release, and agents potentiating the action of vasopressin.¹⁵ In other instances, the mechanism is unknown (Fig. 8.8). The increased use of desmopressin for nocturia in the elderly and enuresis in the young has resulted in a marked increase of reported cases of hyponatremia in these subjects.¹⁶ With the increasing use of intravenous immune globulin (IVIG) as a therapeutic modality in many disorders, cases of hyponatremia associated with its use have been described.¹⁷ The mechanism of IVIG-associated hyponatremia is multifactorial, involving pseudohyponatremia as the protein concentration increases, translocation because of the sucrose in the solution, and true dilutional hyponatremia related to retention of water, particularly in those with associated acute kidney injury.¹⁶

Syndrome of Inappropriate ADH Secretion Despite being the most common cause of hyponatremia in hospitalized patients, the syndrome of inappropriate ADH secretion (SIADH) is a diagnosis of exclusion. A defect in osmoregulation causes vasopressin to be inappropriately stimulated, leading to urinary concentration. The common causes of this syndrome are listed in Figure 8.9.

A few causes deserve special mention. Central nervous system (CNS) disturbances such as hemorrhage, tumors, infections, and trauma cause SIADH by excess vasopressin secretion. Small cell lung cancer, cancer of the duodenum and pancreas, and olfactory neuroblastoma cause ectopic production of vasopressin. Idiopathic cases of SIADH are unusual except in the elderly, in whom as many as 10% of patients have been found to have abnormal vasopressin secretion without known cause.¹⁸

Several patterns of abnormal vasopressin release have emerged from studies of patients with clinical SIADH.¹ In one third of patients with SIADH, vasopressin release varies appropriately

Drugs Associated with Hyponatremia*	
Vasopressin Analogues	Drugs that Potentiate Renal Action of Vasopressin

with serum $[Na^+]$ but begins at a lower threshold of serum osmolality, implying a “resetting of the osmostat.” Ingestion of free water then leads to water retention to maintain the serum $[Na^+]$ at a new lower level, usually 125 mmol/l to 130 mmol/l. In two thirds of patients, vasopressin release does not correlate with serum $[Na^+]$, but a solute-free urine cannot be excreted; therefore, ingested water is retained, giving rise to moderate nonedematous volume expansion and dilutional hyponatremia. In approximately 10% of patients, vasopressin levels are not measurable, suggesting that the syndrome of inappropriate antidiuresis (SIAD) is a more accurate term.¹⁹ Such patients may have a nephrogenic syndrome of antidiuresis, and a gain-of-function mutation in the vasopressin receptor has been suggested as a possible mechanism.²⁰

The diagnostic criteria for SIADH are summarized in Figure 8.10. Plasma vasopressin may be in the “normal” range (up to 10 ng/l), but this is inappropriate given the hypo-osmolar state. In clinical practice, the measurement of plasma vasopressin is rarely needed as the urinary osmolality provides an excellent surrogate bioassay. Thus, a hypertonic urine (>300 mOsm/kg) provides strong evidence for the presence of vasopressin in the circulation because such urinary tonicities are unattainable in its absence. Likewise, a urinary osmolality lower than 100 mOsm/kg reflects the virtual absence of the hormone. Urinary osmolalities in the range of 100 mOsm/kg to 300 mOsm/kg can occur in the presence or absence of the hormone.

Causes of the Syndrome of Inappropriate ADH Release (SIADH)			
Carcinomas	Pulmonary Disorders	Nervous System Disorders	Other
<i>Bronchogenic carcinoma</i>	<i>Viral pneumonia</i>	<i>Encephalitis (viral or bacterial)</i>	<i>AIDS–HIV</i>

Diagnostic Criteria for the Syndrome of Inappropriate ADH Release	
Essential Diagnostic Criteria	
Decreased extracellular fluid effective osmolality (<270 mOsm/kg H ₂ O)	
Inappropriate urinary concentration (>100 mOsm/kg H ₂ O)	
Clinical euvolemia	
Elevated urinary Na ⁺ concentration under conditions of normal salt and water intake	
Absence of adrenal, thyroid, pituitary, or renal insufficiency or diuretic use	
Supplemental Criteria	
Abnormal water-load test (inability to excrete at least 90% of a 20-ml/kg water load in 4 hours and/or failure to dilute urine osmolality to <100mOsm/kg)	
Plasma vasopressin level inappropriately elevated relative to the plasma osmolality	
No significant correction of plasma Na ⁺ level with volume expansion, but improvement after fluid restriction	

Figure 8.10 Diagnostic criteria for the syndrome of inappropriate ADH release (SIADH). (Modified from reference 21.)

Clinical Manifestations of Hyponatremia

Most patients with a serum Na⁺ concentration above 125 mmol/l are asymptomatic. Below 125 mmol/l, headache, yawning, lethargy, nausea, reversible ataxia, psychosis, seizures, and coma may occur as a result of cerebral edema. Rarely, hypotonicity leads to cerebral edema so severe that there is increased intracerebral pressure, tentorial herniation, respiratory depression, and death. Hyponatremia-induced cerebral edema usually occurs with rapid development of hyponatremia, typically in hospitalized postoperative patients receiving diuretics or hypotonic fluids. Untreated severe hyponatremia has a mortality up to 50%. Neurologic symptoms in a hyponatremic patient call for immediate attention and treatment.

The development of cerebral edema largely depends on the cerebral adaptation to hypotonicity. Decreases in extracellular osmolality cause movement of water into cells, increasing intracellular volume and causing tissue edema. The water channel AQP4 appears to play a key role in the movement of water across the blood-brain barrier, as knockout mice for AQP4 are protected from hyponatremic brain swelling,²² whereas animals overexpressing the water channel have exaggerated brain swelling.²³ Cellular edema within the fixed confines of the cranium causes an increase in intracranial pressure, leading to the neurologic syndrome. In most patients with hyponatremia, mechanisms of volume regulation prevent cerebral edema.

Early in the course of hyponatremia (within 1 to 3 hours), a decrease in cerebral extracellular volume occurs by movement of fluid into the cerebrospinal fluid, which is then shunted back into the systemic circulation. This happens promptly and is evident by the loss of extracellular solutes Na⁺ and Cl⁻ as early as 30 minutes after the onset of hyponatremia (Fig. 8.11). If hyponatremia persists for longer than 3 hours, the brain adapts by losing cellular osmolytes, including K⁺ and organic solutes, which tend

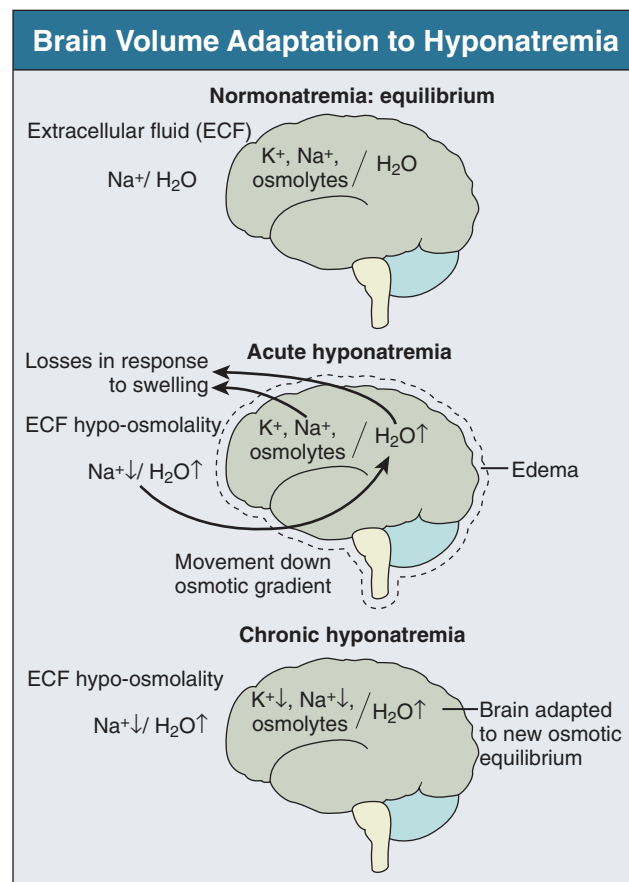

Figure 8.11 Brain volume adaptation to hyponatremia. Under normal conditions, brain osmolality and extracellular fluid (ECF) osmolality are in equilibrium. After the induction of ECF hypo-osmolality, water moves into the brain down osmotic gradients, producing brain edema. In response, the brain loses both extracellular and intracellular solutes (see text for details). As water losses accompany the losses of brain solute, the expanded brain volume then decreases back to normal. In chronic hyponatremia, the brain volume eventually normalizes completely, and the brain becomes fully adapted to the ECF hyponatremia. (Modified from reference 24.)

to lower the osmolality of the brain without substantial gain of water. Thereafter, if hyponatremia persists, other organic osmolytes, such as phosphocreatine, myoinositol, and amino acids (e.g., glutamine, taurine), are lost. The loss of these solutes markedly decreases cerebral swelling. It is because of these adaptations that some subjects, particularly the elderly, may have minimal symptoms despite severe ([Na⁺] <125 mmol/l) hyponatremia.

Certain patients are at increased risk for development of acute cerebral edema in the course of hyponatremia (Fig. 8.12). For example, hospitalized premenstrual women with hyponatremia are more symptomatic and more likely to have complications of therapy than are postmenopausal women or men. This increased risk is independent of the rate of development or the magnitude of hyponatremia. The best management of these patients is to avoid the administration of hypotonic fluids in the postoperative setting. Hyponatremia may occur in the postoperative state even if isotonic fluid is being used if the concentration of Na⁺ and K⁺ in the urine exceeds that in the serum; the hyponatremia is mild and not associated with cerebral dysfunction.¹¹ Children are

Hyponatremic Patients at Risk for Neurologic Complications	
Acute Cerebral Edema	Osmotic Demyelination Syndrome (Central Pontine Myelinolysis)

Marathon runners	Elderly women taking thiazides
	Hypoxemic patients
	[Na ⁺] <105 mmol/l

Figure 8.12 Hyponatremic patients at risk for neurologic complications. (From reference 25.)

particularly vulnerable to the development of acute cerebral edema, perhaps because of a relatively high ratio of brain to skull volume.

Another neurologic syndrome can occur in hyponatremic patients and is a complication of correction of hyponatremia. Osmotic demyelination most commonly affects the central pons of the brainstem and is therefore also termed central pontine myelinolysis. It occurs in all ages; those at most risk are shown in Figure 8.12. It is especially common after liver transplantation, with a reported incidence of 13% to 29% at autopsy. The risk of central pontine myelinolysis is related to the severity and chronicity of the hyponatremia. It rarely occurs with serum [Na⁺] above 120 mmol/l and if hyponatremia is acute in onset (<48 hours). The symptoms are biphasic. Initially, there is a generalized encephalopathy associated with rapid correction of serum [Na⁺]. Two to 3 days after correction, there are behavioral changes, cranial nerve palsies, and progressive weakness culminating in quadriplegia and a locked in syndrome. On T2-weighted magnetic resonance imaging, there are nonenhancing and hyperintense pontine and extrapontine lesions. As these lesions may not appear until 2 weeks after development, a diagnosis of myelinolysis should not be excluded if the imaging is initially normal. The pathogenesis of this syndrome is uncertain; one suggestion is that sodium-coupled amino acid transporters (SNAT2) are down-regulated by hypotonicity, thereby delaying the return of osmoles to the brain, rendering it more sensitive to the correction of hyponatremia.¹⁶ Although serum Na⁺ and K⁺ concentrations return to normal in a few hours, it takes several days for osmotically active solutes in the brain to reach normal levels. This temporary imbalance causes cerebral dehydration and can lead to a potential breakdown of the blood-brain barrier. Whereas central pontine myelinolysis was originally considered to be uniformly fatal, it is now evident that some neurologic recovery can occur and that milder forms of the disorder occur as well.

Treatment of Hyponatremia

Symptoms and duration of hyponatremia determine treatment. Acutely hyponatremic patients (hyponatremia developing within 48 hours) are at great risk for development of permanent

neurologic sequelae from cerebral edema if the hyponatremia remains uncorrected. Patients with chronic hyponatremia are at risk for osmotic demyelination if the hyponatremia is corrected too rapidly.

Acute Symptomatic Hyponatremia

Acute symptomatic hyponatremia, especially associated with seizures or other neurologic manifestations, almost always develops in hospitalized patients receiving hypotonic fluids (Fig. 8.13). Treatment should be prompt as the risk of acute cerebral edema far exceeds the risk of osmotic demyelination. Serum [Na⁺] should be ideally corrected by 2 mmol/l per hour until symptoms resolve. It is not necessary to correct the serum [Na⁺] completely, although it does not appear to be unsafe to do so. Correction may be achieved by administration of hypertonic saline (3% NaCl) at the rate of 1 to 2 ml/h per kilogram of body weight.²⁵⁻²⁶ The administration of a loop diuretic like furosemide enhances free water excretion and hastens the normalization of serum [Na⁺]. If the patient presents with severe neurologic symptoms, such as seizures, obtundation, or coma, 3% NaCl may be infused at higher rates (4 to 6 ml/h per kilogram of body weight). Various formulas have been proposed to estimate an increase in serum [Na⁺] after administration of intravenous fluids,¹⁹ but they tend to underestimate the rate of correction.²⁷ Therefore, during treatment with hypertonic saline, the patient should be monitored carefully for changes in neurologic and pulmonary status, and serum electrolytes should be checked frequently, approximately every 2 hours.

Chronic Symptomatic Hyponatremia

If the hyponatremia has taken more than 48 hours to evolve or if the duration is not known, correction should be undertaken with caution (see Fig. 8.13). Controversy exists as to whether it is the rate of correction or the magnitude of correction of hyponatremia that predisposes to neurologic complications. In clinical practice, it is difficult to dissociate these two variables because a rapid correction rate is usually accompanied by a greater absolute magnitude of correction during a given time. There are important principles to guide treatment:²⁵

- Because cerebral water is increased only by approximately 10% in severe chronic hyponatremia, the goal is to increase the serum Na⁺ level by 10% or by approximately 10 mmol/l.
- Do not exceed a correction rate of 1.0 to 1.5 mmol/l in any given hour.
- Do not increase the serum Na⁺ level by more than 8 to 12 mmol/l per 24 hours.

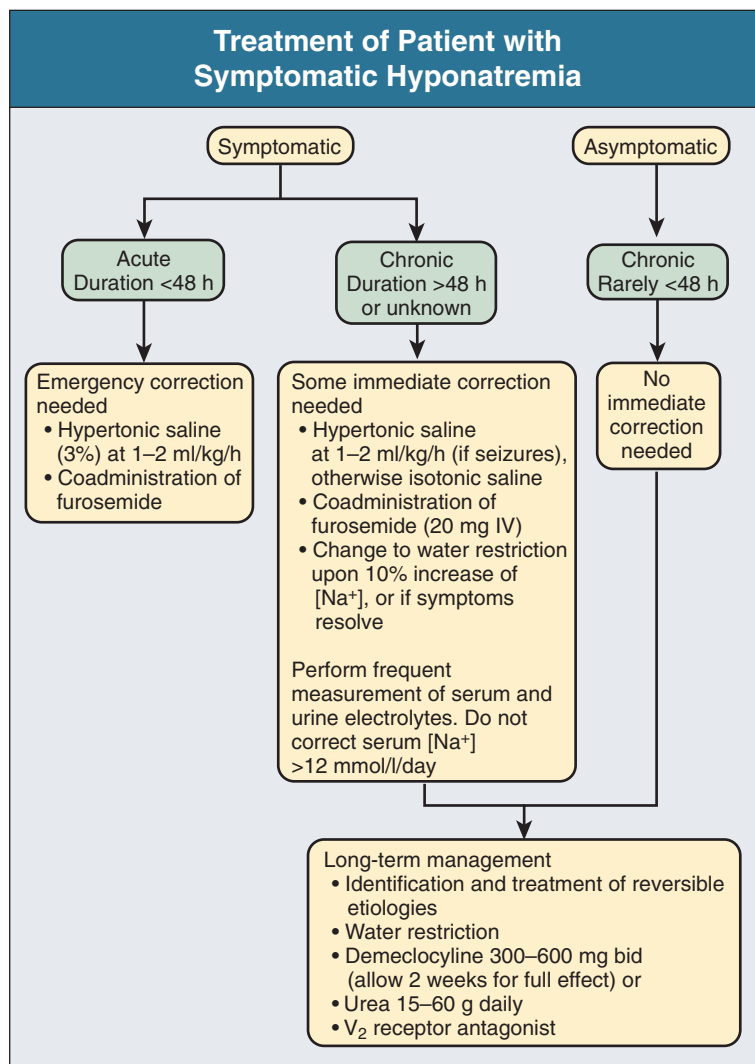

It is important to take into account the rate and electrolyte content of infused fluids and the rate of production and electrolyte content of urine. Once the desired increment in serum Na⁺ concentration is obtained, treatment should consist of water restriction.

If correction has proceeded more rapidly than desired (usually because of excretion of hypotonic urine), the risk of osmotic demyelination may be decreased by relowering serum Na⁺ concentration with intravenous or subcutaneous desmopressin or administration of 5% dextrose.²⁸

Chronic "Asymptomatic" Hyponatremia

Although many patients with chronic hyponatremia appear to be asymptomatic, formal neurologic testing frequently reveals subtle impairments, including gait disturbances comparable to those seen in subjects with toxic levels of alcohol that reverse with correction of the hyponatremia. This results in an increased

Figure 8.13 Treatment of patient with symptomatic hyponatremia. (Modified from reference 25.)

risk for falls and fractures.²⁹ Therefore, even “asymptomatic” patients should be treated in an attempt to restore serum sodium to nearly normal levels. These patients should be evaluated for hypothyroidism, adrenal insufficiency, and SIADH and have their medications reviewed.

Fluid Restriction Fluid restriction is the first-line therapy in patients with chronic asymptomatic hyponatremia (Fig. 8.14). This approach is usually successful if patients are compliant. It involves a calculation of the fluid restriction that will maintain a specific serum Na⁺ concentration. The daily osmolar load (OL) and the minimal urinary osmolality ($U_{\text{osm}}_{\text{min}}$) determine a patient’s maximal urine volume (V_{max}).

$$V_{\text{max}} = \frac{\text{OL}}{(U_{\text{osm}})_{\text{min}}}$$

The value of $(U_{\text{osm}})_{\text{min}}$ is a function of the severity of the diluting disorder. In the absence of circulating vasopressin, it can be as low as 50 mOsm. In a normal North American diet, the daily osmolar load is approximately 10 mOsm/kg (700 mOsm for a 70-kg person). Assuming that a patient with SIADH has a U_{osm} that cannot be lowered to less than 500 mOsm, the same osmolar

load of 700 mOsm allows only 1.4 liters of urine to be excreted per day. Therefore, if the patient drinks more than 1.4 liters per day, the serum Na⁺ concentration will decrease. Measurement of urine Na⁺ and K⁺ concentrations can indicate the degree of water restriction required in a given patient.³⁰ If the diluting defect is so severe that fluid restriction to less than 1 liter is necessary or if the patient’s serum Na⁺ concentration remains low (<130 mmol/l), an alternative approach to treatment, such as increasing solute excretion or pharmacologic inhibition of vasopressin, should be considered.

Maneuvers That Increase Solute Excretion If the patient remains unresponsive to fluid restriction, solute intake can be increased to facilitate an obligatory increase in excretion of solute and free water.³¹ This can be achieved by increasing oral salt and protein intake in the diet to increase the C_{osm} of the urine. Loop diuretics combined with high sodium intake (2 to 3 g of additional salt) are effective in the management of hyponatremia. A single diuretic dose (40 mg furosemide) is usually sufficient but should be doubled if the diuresis induced in the first 8 hours is less than 60% of the total daily urine output.

The administration of urea increases urine flow by causing an osmotic diuresis. This permits a more liberal water intake

Treatment of Chronic Asymptomatic Hyponatremia				
Treatment	Mechanism of Action	Dose	Advantages	Limitations
Fluid restriction	Decreases availability of free water	Variable	Effective and inexpensive; not complicated	Noncompliance
Pharmacologic inhibition of vasopressin action				
Lithium	Inhibits the kidney's response to vasopressin	900–1200 mg/day	Unrestricted water intake	Polyuria, narrow therapeutic range, neurotoxicity
Demeclocycline	Inhibits the kidney's response to vasopressin	300–600 mg twice daily	Effective; unrestricted water intake	Neurotoxicity, polyuria, photosensitivity, nephrotoxicity
V ₂ receptor antagonist	Antagonizes vasopressin action		Addresses underlying mechanisms	Limited clinical experience
Increased solute (salt) intake				
With furosemide	Increases free water clearance	Titrate to optimal dose; coadministration of 2–3g NaCl	Effective	Ototoxicity, K ⁺ depletion
With urea	Osmotic diuresis	30–60 g/day	Effective; unrestricted water intake	Polyuria, unpalatable, gastrointestinal symptoms

Figure 8.14 Treatment of patients with chronic asymptomatic hyponatremia.

without worsening the hyponatremia and without altering urinary concentration. The dose for urea is usually 30 to 60 g/day. The major limitations are gastrointestinal distress and unpalatability.

Pharmacologic Inhibition of Vasopressin Vaptans are novel oral V₂ receptor antagonists that block vasopressin binding to the collecting duct tubular epithelial cells and increase free water excretion without significantly altering electrolyte excretion. These agents are effective in the treatment of hyponatremia in euvolemic and hypervolemic patients.³² Conivaptan, a V₂ and V_{1a} antagonist, is the only vaptan available for intravenous use.³³ It is used in the treatment of hyponatremia in hospitalized patients with transient SIADH, but treatment should be limited to 4 days because it is a potent CYP3A4 inhibitor. Tolvaptan, an oral V₂ antagonist, is now available in some countries at doses between 15 and 60 mg/day.

An alternative pharmacologic treatment is demeclocycline, 600 to 1200 mg daily given 1 to 2 hours after meals; calcium-, aluminum-, and magnesium-containing antacids should be avoided. Onset of action is usually 3 to 6 days after treatment is begun. Dose should be titrated to the minimum to keep the serum [Na⁺] within the desired range with unrestricted water intake. Skin photosensitivity may develop and tooth or bone abnormalities may occur in children. Polyuria leads to noncompliance, and nephrotoxicity may occur, especially in patients with underlying liver disease. Lithium was previously used to block vasopressin action in the collecting duct but has been superseded by the vaptans and demeclocycline.

Hypovolemic Hyponatremia

When thiazides are prescribed, especially in elderly women, serum [Na⁺] should be monitored and water intake restricted. If hyponatremia develops, the drug needs to be discontinued.

Neurologic syndromes directly related to hyponatremia are unusual in hypovolemic hyponatremia as both Na⁺ and water loss limits any osmotic shifts in the brain. Restoration of ECF volume with crystalloids or colloids interrupts the nonosmotic release of vasopressin. Vasopressin antagonists should not be used in this clinical setting.

Hypervolemic Hyponatremia

Congestive Heart Failure In patients with heart failure, sodium and water restriction is critical. Patients may be treated with a combination of angiotensin-converting enzyme (ACE) inhibitors and diuretics. The increase in cardiac output that follows decreases the neurohumorally mediated processes that limit water excretion. Loop diuretics diminish the action of vasopressin on the collecting tubules, thereby decreasing water reabsorption. Thiazides should be avoided as they impair urinary dilution and may worsen hyponatremia. V₂ antagonists increase serum Na⁺ concentration in patients with heart failure,^{32,34} and correction of serum Na⁺ concentration is associated with better long-term outcomes.³⁵ However, in the much larger randomized controlled EVEREST trial in patients with decompensated heart failure, treatment with tolvaptan did not alter any of the long-term clinical outcomes. In principle, a vaptan with V₁ antagonist activity could have additional benefit in cardiac failure, but this is unproven.

Cirrhosis In patients with cirrhosis, water and sodium restriction is the mainstay of therapy. Loop diuretics increase C_{water} once a negative sodium balance has been achieved. V₂ antagonists increase water excretion accompanied by an increase in serum Na⁺ concentration.³⁴ In one study, satavaptan led to a mean increase in serum Na⁺ concentration of 6.6 mmol/L.³⁶ The response to vaptans in cirrhosis is more attenuated than in patients with SIADH or heart failure, which suggests that vasopressin-independent mechanisms may also contribute to their hyponatremia.³² The administration of V₂ antagonists to patients with liver failure is not associated with decrements in blood pressure. Combined V₁ and V₂ antagonists (e.g., conivaptan) should not be used in this population.

HYPERNATREMIC DISORDERS

Hypernatremia is defined as serum [Na⁺] above 145 mmol/L and reflects serum hyperosmolality. The renal concentrating mechanism represents the first defense mechanism against water depletion and hyperosmolality. The components of the normal concentrating mechanism are shown in Figure 8.15. Disorders of urinary concentration may result from decreased delivery of

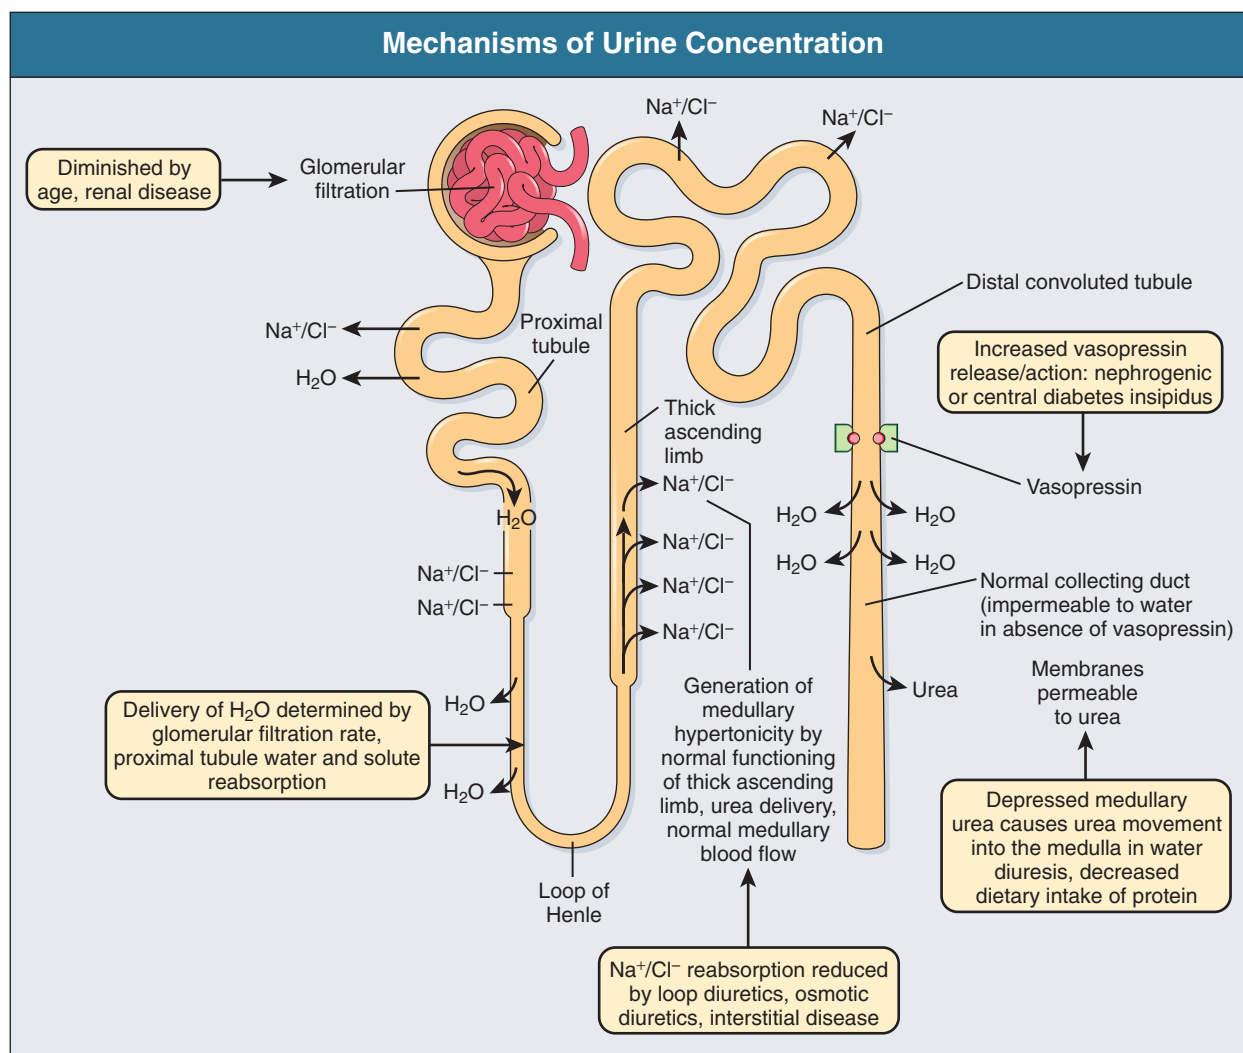

Figure 8.15 Urinary concentrating mechanisms. Determinants of normal urinary concentrating mechanism and disorders causing hyponatremia. (Modified from reference 7.)

solute (with decreasing GFR) or the inability to generate interstitial hypertonicity as a consequence of decreased Na^+ and Cl^- reabsorption in the ascending limb of the loop of Henle (loop diuretics), decreased medullary urea accumulation (poor dietary intake), or alterations in medullary blood flow. Hyponatremia may also result from failure to release or respond to AVP. Thirst is the first and most important defense mechanism in preventing hyponatremia.

Etiology and Classification of Hyponatremia

As with hyponatremia, patients with hyponatremia fall into three broad categories based on volume status.¹⁵ A diagnostic algorithm is helpful in the evaluation of these patients (Fig. 8.16).

Hypovolemia: Hyponatremia Associated with Low Total Body Sodium

Patients with hypovolemic hyponatremia sustain losses of both Na^+ and water, but with a relatively greater loss of water. On physical examination, there are signs of hypovolemia such as orthostatic hypotension, tachycardia, flat neck veins, poor skin turgor, and sometimes altered mental status. Patients will

generally have hypotonic water loss from the kidneys or the gastrointestinal tract; in the latter, the urinary $[\text{Na}^+]$ will be low.

Hypervolemia: Hyponatremia Associated with Increased Total Body Sodium

Hyponatremia with increased total body Na^+ is the least common form of hyponatremia. It results from the administration of hypertonic solutions such as 3% NaCl given as intra-amniotic instillation for therapeutic abortion and NaHCO_3 for the treatment of metabolic acidosis, hyperkalemia, and cardiorespiratory arrest. It may also result from inadvertent dialysis against a dialysate with a high Na^+ concentration or from consumption of salt tablets. Therapeutic hyponatremia is also becoming common as hypertonic saline solutions have emerged as a preferable alternative to mannitol for treatment of increased intracranial pressure.³⁷ Hyponatremia is also increasingly recognized in hypoalbuminemic hospitalized patients with renal failure who are edematous and unable to concentrate their urine.

Euvolemia: Hyponatremia Associated with Normal Body Sodium

Most patients with hyponatremia secondary to water loss appear euvolemic with normal total body Na^+ because loss of

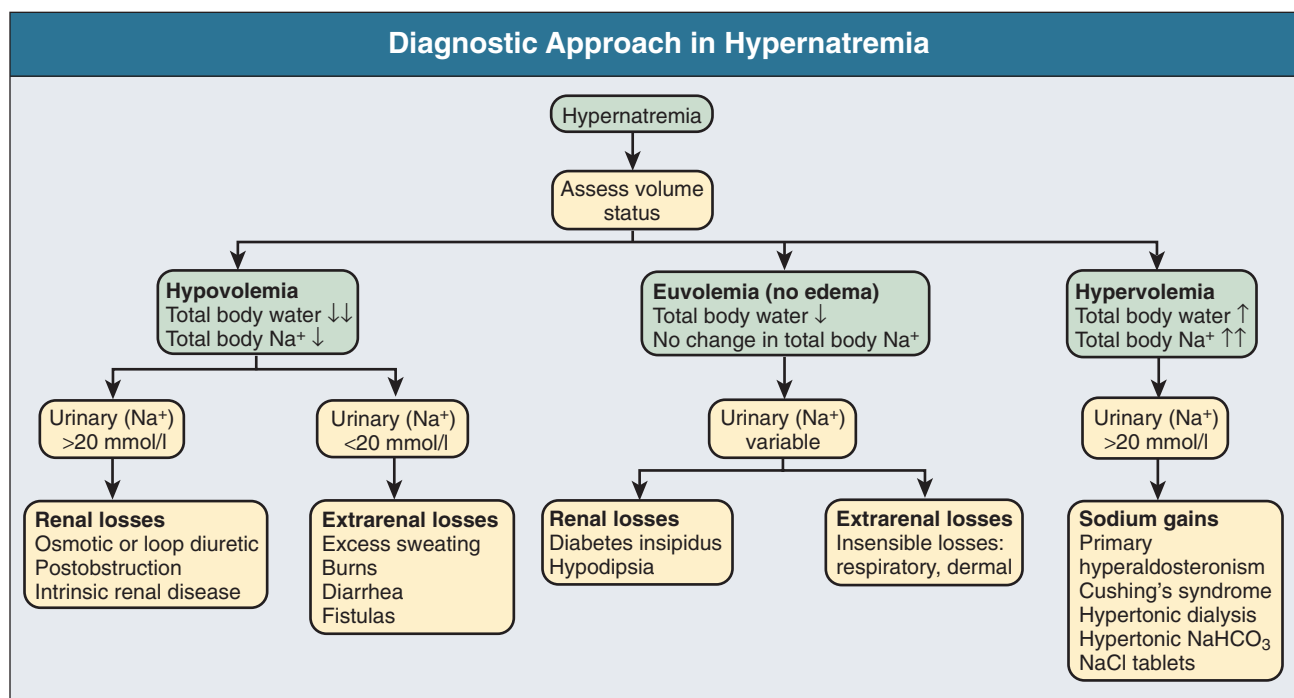

Figure 8.16 Diagnostic approach in hypernatremia. (Modified with permission from reference 5.)

water without Na^+ does not lead to overt volume contraction. Water loss *per se* need not result in hypernatremia unless it is unaccompanied by water intake. Because hypodipsia is uncommon, hypernatremia usually develops only in those who have no access to water and the very young and old, in whom there may be an altered perception of thirst. Extrarenal water loss occurs from the skin and respiratory tract in febrile or other hypermetabolic states and is associated with a high urine osmolality because the osmoreceptor-vasopressin-renal response is intact. The urine Na^+ concentration varies with the intake. Renal water loss leading to euvolemic hypernatremia results either from a defect in vasopressin production or release (central diabetes insipidus) or from a failure of the collecting duct to respond to the hormone (nephrogenic diabetes insipidus). Defense against the development of hyperosmolality requires the appropriate stimulation of thirst and the ability to respond by drinking water.

Polyuric disorders can result from either an increase in C_{osm} or an increase in C_{water} . An increase in C_{osm} occurs with diuretic use, renal salt wasting, excess salt ingestion, vomiting (bicarbonaturia), alkali administration, and administration of mannitol (as a diuretic, for bladder lavage, or for the treatment of cerebral edema). An increase in C_{water} occurs with excess ingestion of water (psychogenic polydipsia) or in abnormalities of the renal concentrating mechanism (diabetes insipidus).

Diabetes Insipidus Diabetes insipidus (DI) is characterized by polyuria and polydipsia and is caused by defects in vasopressin action. Patients with central and nephrogenic DI and primary polydipsia present with polyuria and polydipsia. The differentiation between these entities can be accomplished by clinical evaluation, with measurements of vasopressin levels and the response to a water deprivation test followed by vasopressin administration (Fig. 8.17).

Central Diabetes Insipidus

CLINICAL FEATURES Central DI usually has an abrupt onset. Patients have a constant need to drink, have a predilection for cold water, and commonly have nocturia. By contrast, the compulsive water drinker may give a vague history of the onset and has large variations in water intake and urine output. Nocturia is unusual in compulsive water drinkers. A plasma osmolality of more than 295 mOsm/kg suggests central DI, and a plasma osmolality of less than 270 mOsm/kg suggests compulsive water drinking.

CAUSES Central DI is caused by infection, tumors, granuloma, and trauma affecting the CNS in 50% of the cases; in the other 50%, it is idiopathic (Fig. 8.18). In a survey of 79 children and young adults, central DI was idiopathic in half the cases. The remainder had tumors and Langerhans cell histiocytosis; these patients had an 80% chance for development of anterior pituitary hormone deficiency compared with the patients with idiopathic disease.³⁸

Autosomal dominant DI is caused by point mutations in a precursor gene for vasopressin that cause “misfolding” of the provasopressin peptide, preventing its release from the hypothalamic and posterior pituitary neurons.³⁹ Patients present with a mild polyuria and polydipsia in the first year of life. These children have normal physical and mental development. There is a rare autosomal recessive central DI associated with diabetes mellitus, optic atrophy, and deafness (Wolfram syndrome).⁴⁰ DI is usually partial and gradual in onset in Wolfram syndrome. It is linked to chromosome 4 and involves abnormalities in mitochondrial DNA.

A rare clinical entity is the combination of central DI and deficient thirst. It has been reported in a total of 70 patients in 41 studies.⁴¹ When vasopressin secretion and thirst are both impaired, affected patients are vulnerable to recurrent episodes

Water Deprivation Test			
Condition	Urinary Osmolality with Water Deprivation (mOsm/kg H ₂ O)	Plasma Vasopressin after Dehydration (pg/ml)	Increase in Urinary Osmolality with Exogenous Vasopressin
Normal	>800	>2	Little or no increase
Complete central diabetes insipidus	<300	Undetectable	Substantially increased
Partial central diabetes insipidus	300–800	<1.5	Increase of >10% of urinary osmolality after water deprivation
Nephrogenic diabetes insipidus	<300–500	>5	Little or no increase
Primary polydipsia	>500	<5	Little or no increase

Figure 8.17 Water deprivation test. Test procedure: Water intake is restricted until the patient loses 3% to 5% of his or her body weight or until three consecutive hourly determinations of urinary osmolality are within 10% of each other. (Caution must be exercised to ensure that the patient does not become excessively dehydrated.) Aqueous vasopressin (5 U subcutaneously) is given, and urinary osmolality is measured after 60 minutes. The expected responses are given in the table. (From reference 42.)

Causes of Central Diabetes Insipidus	
Congenital	
Autosomal dominant	
Autosomal recessive	
Acquired	
<i>Post-traumatic</i>	
<i>Iatrogenic (postsurgical)</i>	
<i>Tumors (metastatic from breast, craniopharyngioma, pinealoma)</i>

Granuloma (tuberculosis, sarcoid)	
Aneurysm	
Meningitis	
Encephalitis	
Guillain-Barré syndrome	
Idiopathic	

Figure 8.18 Causes of central diabetes insipidus. Entries in italics are the common causes.

of hypernatremia. Formerly called essential hypernatremia, the disorder is now called central DI with deficient thirst or adipsic DI.

DIFFERENTIAL DIAGNOSIS Measurement of circulating vasopressin by radioimmunoassay is preferred to the tedious water deprivation test. Under basal conditions, vasopressin levels are unhelpful because there is a significant overlap among the polyuric disorders. Measurement after a water deprivation test is more useful (see Fig. 8.17).

TREATMENT Central DI is treated with hormone replacement or pharmacologic agents (Fig. 8.19). In acute settings, when renal water losses are extensive, aqueous vasopressin (Pitressin) is useful. It has a short duration of action, allows careful monitoring, and avoids complications such as water intoxication. This drug should be used with caution in patients with underlying coronary artery disease and peripheral vascular disease as it may cause

vascular spasm and prolonged vasoconstriction. For chronic central DI, desmopressin acetate is the agent of choice. It has a long half-life and does not have the significant vasoconstrictive effects of aqueous vasopressin. It is administered at the dose of 10 to 20 µg intranasally every 12 to 24 hours. It is tolerated well, safe to use in pregnancy, and resistant to degradation by circulating vasopressinase. Oral desmopressin (0.1 to 0.8 mg every 12 hours) is available as second-line therapy. In patients with partial DI, in addition to desmopressin itself, agents that potentiate the release of vasopressin may be used. These agents include chlorpropamide, clofibrate, and carbamazepine.

Congenital Nephrogenic Diabetes Insipidus Inherited forms of DI are due to mutations in genes for aquaporins or vasopressin receptors. Urine volumes are typically very high, and there is a risk for severe hypernatremia if patients do not have free access to water. These entities are discussed further in Chapter 47.

Acquired Nephrogenic Diabetes Insipidus Acquired nephrogenic DI is more common than and rarely as severe as congenital nephrogenic DI. In these patients, the ability to elaborate a maximal concentration of urine is impaired, but urinary concentrating mechanisms are partially preserved. For this reason, urinary volumes are less than 3 to 4 l/day, which contrasts with the much higher volumes seen in patients with congenital or central DI or compulsive water drinking. The causes and mechanisms of acquired nephrogenic DI are listed in Figure 8.20.

CHRONIC KIDNEY DISEASE A defect in urinary concentrating ability may develop in patients with chronic kidney disease of any etiology, but this defect is most prominent in tubulointerstitial diseases, particularly medullary cystic disease. Disruption of inner medullary structures and diminished medullary concentration are thought to play a role; alterations in V₂ receptor and AQP2 expression also contribute (see Fig. 8.7). To achieve daily osmolar clearance, an amount of fluid commensurate with the severity of the concentrating defect is necessary in patients who still make urine. Patients should be advised to maintain a fluid intake that matches their urine volume.

ELECTROLYTE DISORDERS Hypokalemia causes a reversible abnormality in urinary concentrating ability. Hypokalemia stimulates water intake and reduces interstitial tonicity, which relates

Treatment of Central Diabetes Insipidus			
Disease	Drug	Dose	Interval
Complete central diabetes insipidus	Desmopressin (DDAVP)	10–20 µg intranasally	12–24 h
	Desmopressin (DDAVP)	0.1–0.8 mg orally	Every 12 h
Partial central diabetes insipidus	Desmopressin (DDAVP)	10–20 µg intranasally	12–24 h
	Aqueous vasopressin	5–10 U subcutaneously	4–6 h
	Chlorpropamide	250–500 mg	24 h
	Clofibrate	500 mg	6 or 8 h
	Carbamazepine	400–600 mg	24 h

Lithium therapy	—	Yes	Yes	—
Pregnancy	—	—	—	Placental secretion of vasopressinase

Figure 8.20 Acquired nephrogenic diabetes insipidus: causes and mechanisms. cAMP, cyclic adenosine monophosphate.

to the decreased Na⁺-Cl⁻ reabsorption in the TALH. Hypokalemia resulting from diarrhea, chronic diuretic use, and primary aldosteronism also decreases intracellular cyclic adenosine monophosphate accumulation and causes a reduction in vasopressin-sensitive AQP2 expression (see Fig. 8.7).

Hypercalcemia also impairs urinary concentrating ability, resulting in mild polydipsia. The pathophysiologic mechanism is multifactorial and includes a reduction in medullary interstitial tonicity caused by decreased vasopressin-stimulated adenylate cyclase in the TALH and a defect in adenylate cyclase activity with decreased AQP2 expression in the collecting duct.

PHARMACOLOGIC AGENTS Lithium is the most common cause of nephrogenic DI, occurring in up to 50% of patients receiving long-term lithium therapy. Lithium causes downregulation of AQP2 in the collecting duct; experimentally, it also increases cyclooxygenase 2 (COX-2) expression and urinary prostaglandins, which may contribute to the polyuria.⁴³ The concentrating defect of lithium may persist even when the drug is discontinued. The epithelial sodium channel, ENaC, is the entrance pathway for lithium into collecting duct principal cells. Amiloride inhibits lithium uptake through ENaC and has been used clinically to treat nephrogenic DI caused by lithium. Aldosterone administration dramatically increases urine production in experimental nephrogenic DI due to lithium⁴⁴ (an effect that is associated with decreased expression of AQP2 on luminal membranes of the collecting duct), whereas administration of the

mineralocorticoid receptor blocker spironolactone decreased urine output and increased AQP2 expression.⁴⁵ It is not yet known if spironolactone is a useful treatment for humans with lithium-induced nephrogenic DI.

Other drugs impairing urinary concentrating ability include amphotericin, foscarnet, and demeclocycline, which reduces renal medullary adenylate cyclase activity, thereby decreasing the effect of vasopressin on the collecting ducts.

SICKLE CELL ANEMIA Patients with sickle cell disease and trait often have a urinary concentrating defect. In the hypertonic medullary interstitium, the “sickled” red cells cause occlusion of the vasa recta and papillary damage. The resultant medullary ischemia may impair Na⁺-Cl⁻ transport in the ascending limb and diminish medullary tonicity. Although initially reversible, medullary infarcts occur with long-standing sickle cell disease and the concentrating defects become irreversible.

DIETARY ABNORMALITIES Extensive water intake or a marked decrease in salt and protein intake leads to impairment of maximal urinary concentrating ability through a reduction in medullary interstitial tonicity. On a low-protein diet with excessive water intake, there is a decrease in vasopressin-stimulated osmotic water permeability that is reversed with feeding.

Gestational Diabetes Insipidus In gestational DI, there is an increase in circulating vasopressinase, which is produced

by the placenta. Patients are typically unresponsive to vasopressin but respond to desmopressin, which is resistant to vasopressinase.

Clinical Manifestations of Hypernatremia

Certain patients are at increased risk for development of severe hypernatremia (Fig. 8.21). Signs and symptoms mostly relate to the CNS and include altered mental status, lethargy, irritability, restlessness, seizures (usually in children), muscle twitching, hyperreflexia, and spasticity. Fever, nausea or vomiting, labored breathing, and intense thirst can also occur. In children, the mortality of acute hypernatremia ranges between 10% and 70%.

Patient Groups at Risk for Development of Severe Hypernatremia	
Elderly patients or infants	
Hospitalized patients receiving hypertonic infusions, tube feedings, osmotic diuretics, lactulose, mechanical ventilation	
Altered mental status	
Uncontrolled diabetes mellitus	
Underlying polyuric disorders	

Figure 8.21 Patient groups at risk for development of severe hypernatremia. (From reference 25.)

As many as two thirds of survivors have neurologic sequelae. In contrast, mortality in chronic hypernatremia is 10%. In adults, serum Na^+ concentrations above 160 mmol/l are associated with a 75% mortality, although this may reflect associated comorbidities rather than hypernatremia *per se*.

Treatment of Hypernatremia

Hypernatremia occurs in predictable clinical settings, allowing opportunities for prevention. Elderly and hospitalized patients are at high risk because of impaired thirst and inability to access free water independently.⁴⁶ Certain clinical situations, such as recovery from acute kidney injury, catabolic states, therapy with hypertonic solutions, uncontrolled diabetes, and burns, should prompt close attention to serum sodium concentration and increased administration of free water.

Hypernatremia always reflects a hyperosmolar state. The primary goal in the treatment of these patients is the restoration of serum tonicity. The treatment regimen depends on the volume status. Specific management options are outlined in Figure 8.22.²⁵

The rapidity with which hypernatremia should be corrected is a matter of controversy. Some animal studies and case series in pediatric patients suggest that a correction rate of more than 0.5 mmol/l per hour in $[\text{Na}^+]$ can cause seizures. Cerebral edema also can be caused by rapid correction of hypernatremia by the net movement of water into the brain. Most clinicians believe that even in adults, correction should be achieved during 48 hours at a rate no greater than 2 mmol/l per hour.

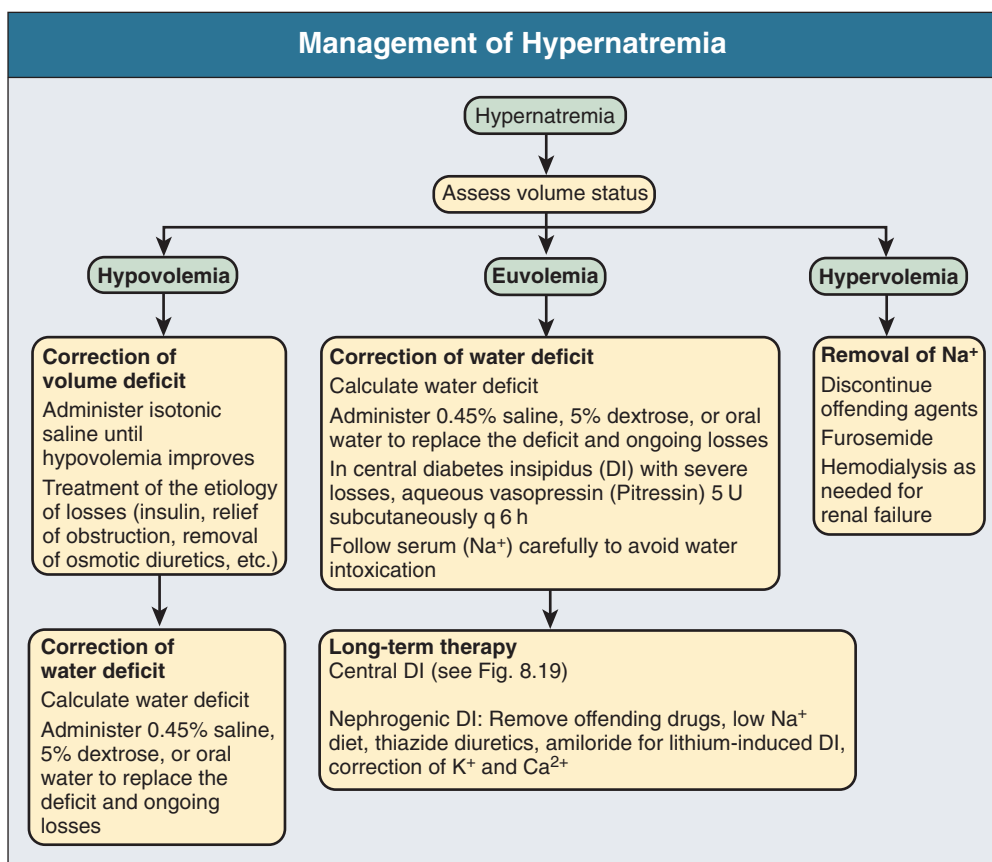

Figure 8.22 Management of hypernatremia. (From reference 25.)

Disorders of Potassium Metabolism

I. David Weiner, Stuart L. Linas, Charles S. Wingo

DEFINITION

Potassium disorders are some of the most commonly encountered fluid and electrolyte abnormalities in clinical medicine. They can be asymptomatic or associated with symptoms ranging from mild weakness to sudden death. When the serum potassium concentration is verified as abnormal, correction is essential, but inappropriate treatment can worsen symptoms and even lead to death.

NORMAL PHYSIOLOGY OF POTASSIUM METABOLISM

Potassium Intake

Potassium is essential for many cellular functions, is present in most foods, and is excreted primarily by the kidney. The typical daily Western diet contains approximately 70 to 150 mmol potassium. The gastrointestinal tract efficiently absorbs potassium, and dietary potassium intake varies greatly with the composition of the diet. [Figure 9.1](#) summarizes the potassium content of several foods high in potassium content.

Potassium Distribution

After absorption from the gastrointestinal tract, potassium distributes into the extracellular and intracellular fluid compartments. Potassium is the major intracellular cation, with values from ~100 to 120 mmol/l in the cytosol, and is distributed primarily intracellularly. Total intracellular potassium content is 3000 to 3500 mmol in healthy adults, which is distributed primarily in muscle (70%), with smaller amounts present in bone, red blood cells, liver, and skin ([Fig. 9.2](#)). Only 1% to 2% of total body potassium is present in the extracellular fluids. The electrogenic sodium pump, Na^+, K^+ -ATPase, effects this asymmetric potassium distribution by active uptake, which occurs in virtually all cells. Na^+, K^+ -ATPase transports two potassium ions into cells in exchange for extrusion of three sodium ions, which results in high intracellular potassium and low intracellular sodium activity. The ratio of intracellular to extracellular potassium concentration is a major determinant of cell membrane potential and intracellular electronegativity due to the action of potassium-selective ion channels. Normal maintenance of this ratio and membrane potential is critical for normal nerve conduction and muscle contraction.

Serum potassium concentration is tightly regulated through multiple mechanisms. Studies support a “feed forward” regulatory system involving gut or portal potassium sensors. This system adjusts renal potassium excretion through mechanisms independent of serum potassium and aldosterone.^{1,2} This reflex

system, which is still not understood fully, allows the kidney to “sense” dietary intake and to alter renal potassium excretion despite no discernible changes in plasma potassium or aldosterone concentration.

In addition, several hormones and factors can induce potassium shifts between the extracellular and intracellular potassium pools ([Fig. 9.3](#)). The most common causes include acid-base disorders, specific hormones, plasma osmolality, and exercise.

Acidosis due to inorganic anions, such as NH_4Cl and HCl , can cause hyperkalemia, but the mechanism is not fully understood. In contrast, organic acids (such as lactic acid), in general, do not cause transcellular potassium shifts. Insulin and β_2 -adrenergic receptor activation induce cellular potassium uptake by stimulating Na^+, K^+ -ATPase. Insulin directly stimulates the Na^+, K^+ -ATPase pump through a mechanism separate from its stimulation of glucose entry. β_2 -Adrenergic receptor activation increases intracellular cyclic adenosine monophosphate production, which stimulates Na^+, K^+ -ATPase-mediated potassium uptake. α -Adrenergic activation opposes the effect of β_2 -adrenergic receptor stimulation. The effects of insulin and β_2 -adrenergic receptor activation are synergistic, as expected given the differing cellular mechanisms.

Aldosterone lowers serum potassium concentration by two major mechanisms. Aldosterone stimulates potassium movement into cells (redistribution), and it increases potassium excretion in the kidney and, to a lesser extent, in the gut. The primary renal action of aldosterone is to stimulate sodium reabsorption; but with ample sodium delivery to the late distal nephron and collecting duct, this promotes enhanced flow-dependent potassium excretion.

Hyperosmolality, if it is due to effective osmoles, can induce potassium shifts out of cells and result in hyperkalemia. The proposed mechanism is that increased plasma osmolality induces water movement out of the cells, which decreases cell volume and increases intracellular potassium concentrations. This is then thought to result in feedback inhibition of Na^+, K^+ -ATPase, shifting potassium from the intracellular to the extracellular compartment and normalizing intracellular potassium concentration. The clinician should remember that this occurs only with effective osmoles, such as hyperglycemia in persons with diabetes or with mannitol. Both glucose, in a patient with intact insulin secretion, and urea are ineffective osmoles because they rapidly cross plasma membranes and therefore do not alter cell volume. Importantly, hyperglycemia in a nondiabetic patient, if it stimulates endogenous insulin secretion or if exogenous insulin is given, can cause insulin-induced cellular potassium uptake and resultant hypokalemia.

Exercise may result in hyperkalemia by α -adrenergic receptor activation that shifts potassium out of the skeletal muscle cells. The increased serum potassium induces arterial dilation, which

Potassium Content of Selected High-Potassium Foods		
Food	Portion Size	mmol K ⁺
Artichoke, boiled	1, medium	27
Avocado	1, medium	38
Sirloin steak	8 oz	23
Hamburger, lean	8 oz	18

Distribution of Total Body Potassium in Organs and Body Compartments			
Organs and Compartments		Body Compartment Concentrations	
Muscle	2650 mmol	Intracellular concentration	150 mmol/l
Liver	250 mmol	Extracellular concentration	4 mmol/l
Interstitial fluid	35 mmol		
Red blood cells	35 mmol		
Plasma	15 mmol		

Figure 9.2 Distribution of total body potassium in organs and body compartments.

increases skeletal muscle blood flow and acts as an adaptive mechanism during exercise. Simultaneous β_2 -adrenergic receptor activation stimulates skeletal muscle cellular potassium uptake and minimizes the severity of exercise-induced hyperkalemia, but this can lead to hypokalemia after the cessation of exercise. In patients with preexisting potassium depletion, post-exercise hypokalemia may be severe and rhabdomyolysis may occur.³

Renal Potassium Handling with Normal Renal Function

Long-term potassium homeostasis is accomplished primarily through changes in renal potassium excretion and here almost entirely through regulated collecting duct potassium transport. Serum potassium is almost completely ionized, is not bound to plasma proteins, and is filtered efficiently by the glomerulus (Fig. 9.4). The proximal tubule reabsorbs the majority (~65% to 70%)

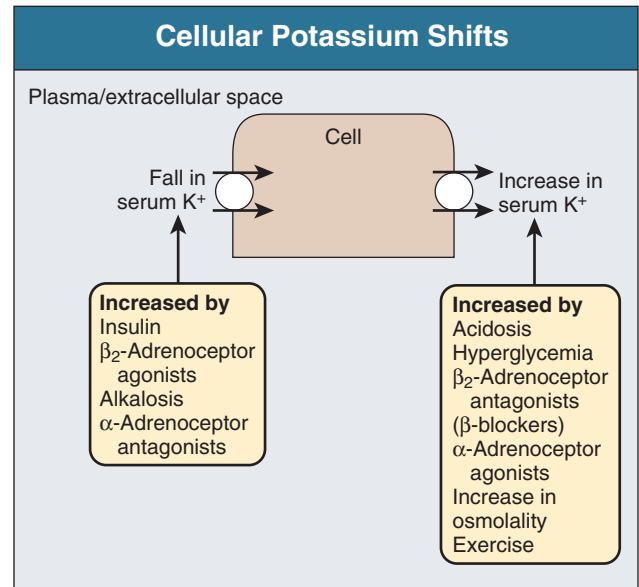

Figure 9.3 Regulation of extracellular-intracellular potassium shifts.

Figure 9.4 Renal handling of potassium.

of filtered potassium. Very little regulation occurs in response to changes in dietary potassium intake. Potassium is secreted by the descending loop of Henle, at least in deep nephrons, and is reabsorbed by the ascending loop of Henle through the action of the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter (Fig. 9.5A). This results in modest net potassium reabsorption in the loop of Henle. This absorption can be reversed to secretion, however, by administration of a loop diuretic or by substantial potassium loading.

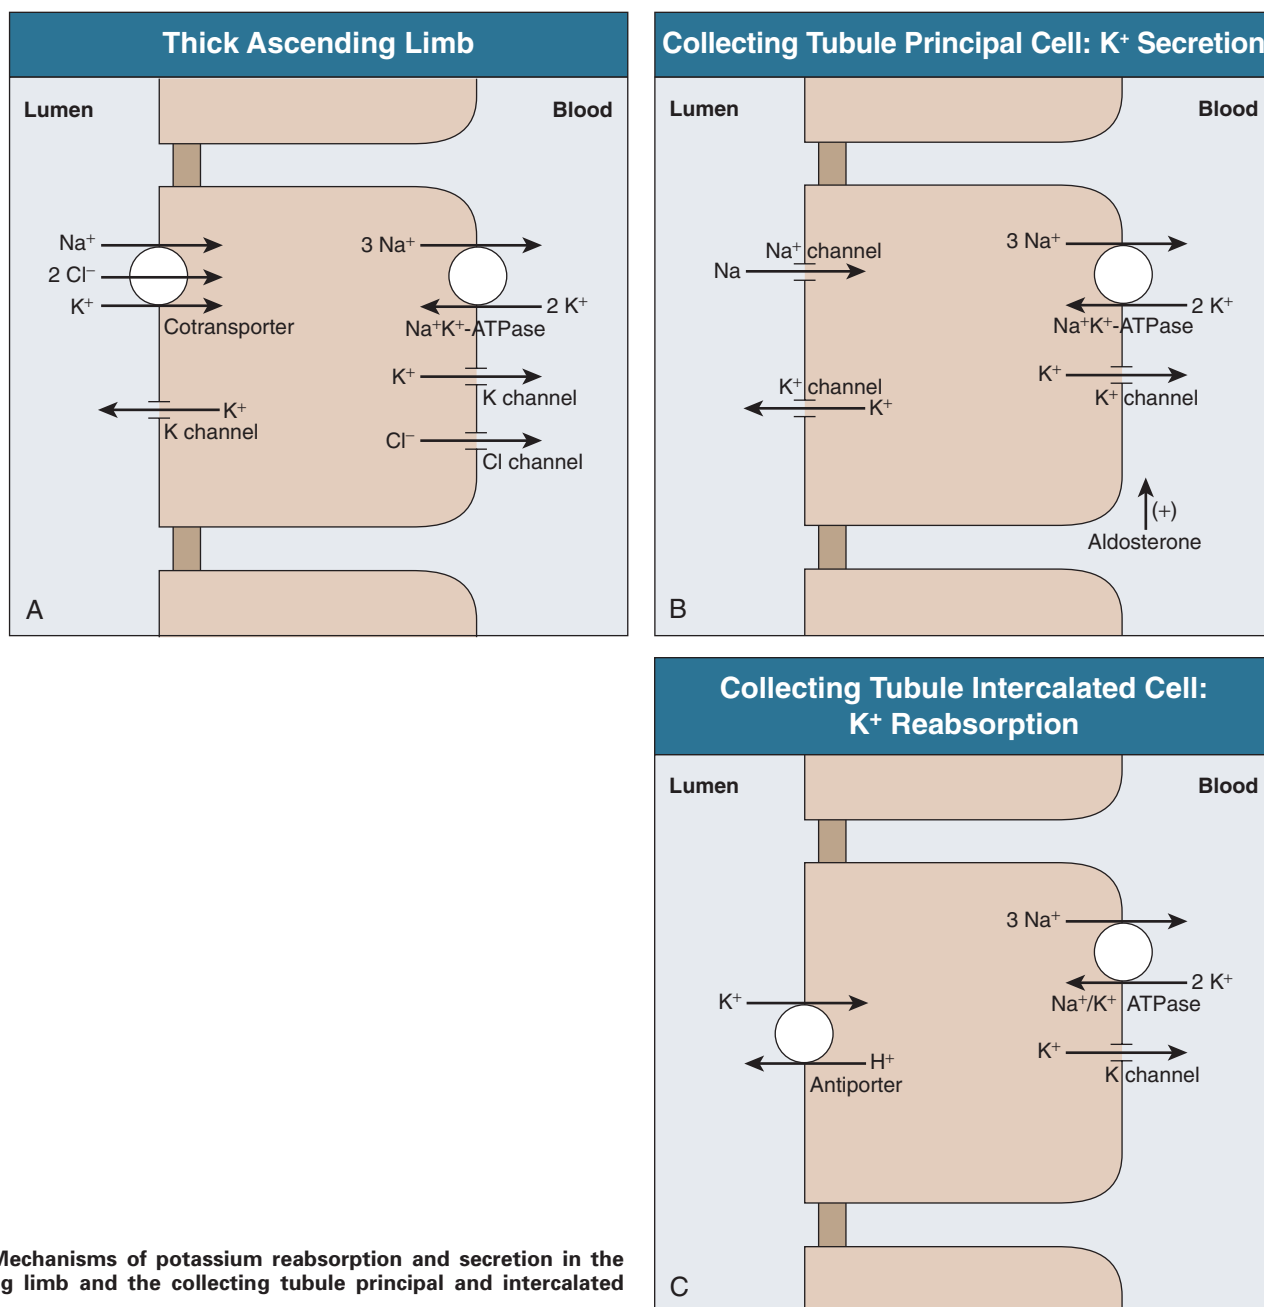

Figure 9.5 Mechanisms of potassium reabsorption and secretion in the thick ascending limb and the collecting tubule principal and intercalated cells.

Nevertheless, the majority of potassium excretion is regulated normally through active secretion and absorption in the distal tubule and collecting duct.

Collecting duct potassium transport occurs through distinct cell types that allow fine control of renal potassium excretion. The principal cell of the cortical collecting duct secretes potassium (Fig. 9.5B). Sodium reabsorption through the apical sodium channel (ENaC) stimulates basolateral $\text{Na}^+\text{K}^+\text{-ATPase}$, and the active turnover of this pump maintains high intracellular potassium concentrations. Subsequent to basolateral potassium uptake, potassium is secreted into the luminal fluid by apical potassium channels and KCl cotransporters. Intercalated cells reabsorb potassium through an apical $\text{H}^+\text{K}^+\text{-ATPase}$ (Fig. 9.5C).⁴ This protein actively secretes H^+ into the luminal fluid in exchange for potassium, resulting in potassium reabsorption. The presence

of two separate potassium transport processes, secretion by principal cells and reabsorption by intercalated cells, enables effective regulation of renal potassium excretion.

Several factors regulate principal cell potassium secretion. In relative order of importance, these are luminal flow rate, distal sodium delivery, aldosterone, extracellular potassium, and extracellular pH. An increase in luminal flow rate reduces luminal potassium concentration, thereby increasing the concentration gradient across the apical membrane, which stimulates potassium secretion. In addition, flow rate directly influences cellular potassium secretion, possibly by modulating the activity of potassium channels. Conversely, reduced luminal flow, such as occurs in prerenal states or obstruction, may result in hyperkalemia. Decreased sodium reabsorption, whether from reduced luminal sodium delivery or from sodium channel inhibitors, decreases

potassium secretion by altering electrochemical forces for potassium secretion. “Potassium-sparing diuretics,” either directly or indirectly, reduce sodium reabsorption and thereby inhibit potassium secretion. Increased sodium delivery to the collecting duct, such as may occur with loop or thiazide diuretics, increases principal cell sodium reabsorption and causes a secondary increase in potassium secretion. Aldosterone has many effects that increase principal cell potassium secretion. These include increases in Na^+, K^+ -ATPase expression and increased apical expression of the sodium channel ENaC. The net effect is increased potassium secretion. Increasing extracellular potassium directly stimulates Na^+, K^+ -ATPase activity, leading to increased potassium secretion. Metabolic acidosis decreases potassium secretion both through direct effects on potassium channels and through changes in interstitial ammonia concentration, which then decreases potassium secretion.⁵ Respiratory acid-base disorders in general have little effect on potassium secretion.

Potassium reabsorption, which decreases renal potassium excretion, occurs through the action of the active potassium-reabsorbing transporter H^+, K^+ -ATPase. The major factors regulating H^+, K^+ -ATPase expression and activity include potassium balance, aldosterone, and acid-base status. Potassium depletion increases H^+, K^+ -ATPase expression, which then results in increased active potassium reabsorption and decreased potassium excretion. Aldosterone is a second factor that increases H^+, K^+ -ATPase expression and activity. This may, by decreasing net potassium excretion, serve as a “counterbalancing factor” to minimize the hypokalemia that results generally from increased aldosterone. Metabolic acidosis has both direct and indirect (mediated through alterations of ammonia metabolism) effects that increase H^+, K^+ -ATPase potassium transport. In some cases, this may contribute to the hyperkalemia that can occur with metabolic acidosis.

Intracellular kinases of a new class that are important for regulating renal potassium physiology in the distal nephron have recently been identified. The WNK (with no lysine) kinases are a family of proteins expressed in many cells of the body, including the kidney. Under basal conditions, several WNK kinases prevent sodium reabsorption (in part by downregulation of the Na^+-Cl^- cotransporter [NCC] and paracellular sodium flux) as well as potassium secretion (in part by inhibition of the renal outer medullary potassium channel [ROMK]). Genetic defects that inactivate several WNK kinases result in enhanced sodium reabsorption and reduced potassium secretion.

Renal Potassium Handling in Chronic Kidney Disease

Potassium homeostasis is relatively well preserved and serum potassium concentration usually remains in the normal range until glomerular filtration rate (GFR) is reduced substantially. This adaptation is due to increased potassium excretion per nephron in the connecting segment and the collecting duct. Both aldosterone and an increase in serum potassium may contribute to this adaptation. Intestinal potassium secretion increases also, although this is less important quantitatively.

Patients with chronic kidney disease (CKD) have more difficulty handling an acute potassium load, even when they have a normal serum potassium concentration. Because these patients have decreased nephron number, their maximal capacity for potassium secretion is limited. Patients with CKD are also routinely treated with medications that alter renal potassium handling, such as angiotensin-converting enzyme (ACE) inhibitors,

angiotensin receptor blockers (ARBs), and β -adrenergic receptor blockers. These can decrease renal potassium sensitivity and result in higher serum potassium concentrations.

Patients with CKD generally tolerate hyperkalemia with fewer cardiac and electrocardiographic abnormalities than patients with normal renal function do. The mechanism of this adaptation is incompletely understood. Nevertheless, severe hyperkalemia (>6.0 mmol/l or the presence of electrocardiographic changes) can have lethal effects and should be treated aggressively.

HYPOKALEMIA

Epidemiology

The incidence of potassium disorders is strongly dependent on the patient population. Less than 1% of adults with normal renal function not receiving medicines develop hypokalemia or hyperkalemia; however, diets with large sodium and small potassium content may lead to potassium depletion. Thus, hypokalemia or hyperkalemia in a healthy adult not taking medicine should suggest an underlying disease. In contrast, hypokalemia frequently occurs in the setting of specific disease states and with the use of medicines that affect renal potassium handling. For example, hypokalemia may be present in up to 50% of patients using diuretics,⁶ and it is present frequently in people with primary or secondary hyperaldosteronism.

Clinical Manifestations

Potassium deficiency alters the function of the heart and blood vessels, nerves, muscles, gut, and kidneys. Overall, children and young adults tolerate hypokalemia better than elderly individuals do. Prompt correction is warranted in the presence of ischemic heart disease or in patients receiving digitalis.

Cardiovascular

Epidemiologic studies link a low-potassium diet with an increased prevalence of hypertension. Hypokalemia has been shown experimentally to increase blood pressure modestly (5 to 10 mm Hg), and similarly, potassium supplementation can lower blood pressure.⁷ Potassium deficiency probably increases blood pressure by stimulating sodium retention, with resultant intravascular volume expansion, and by sensitizing the vasculature to endogenous vasoconstrictors.⁷ In part, sodium retention is related to decreased expression of the kidney-specific isoform of WNK1, which leads to increased NCC- and ENaC-mediated sodium reabsorption in the distal convoluted tubule and cortical collecting duct, respectively.⁸

Hypokalemia increases the risk for a variety of ventricular arrhythmias, including ventricular fibrillation.⁹ Diuretic-induced hypokalemia is of particular concern, as sudden cardiac death may occur more commonly in those treated with thiazide diuretics.⁹ Ventricular arrhythmias are also more common in hypokalemic patients receiving digoxin.

Hormonal

Hypokalemia impairs insulin release and also induces insulin resistance, resulting in worsened glucose control in diabetic patients.¹⁰ Experimental studies have demonstrated that the insulin resistance observed with thiazide diuretics is due to endothelial dysfunction mediated by thiazide-induced hypokalemia and hyperuricemia.^{11,12}

Muscular

Hypokalemia hyperpolarizes skeletal muscle cells, thereby impairing muscle contraction. Hypokalemia also reduces skeletal muscle blood flow, possibly by impairing local nitric oxide release, which can predispose patients to rhabdomyolysis during vigorous exercise.¹³

Renal

Hypokalemia leads to several important disturbances of renal function. These include reduced medullary blood flow and increased renal vascular resistance that may predispose to hypertension, tubulointerstitial and cystic changes, alterations in acid-base balance, and impairment of renal concentrating mechanisms.

Tubulointerstitial and Cystic Changes Potassium depletion causes tubulointerstitial fibrosis that is generally greatest in the outer medulla. Although usually reversible, it may result in renal failure. Experimental studies suggest that there is increased risk for irreversible renal injury in the neonatal period.¹⁴ Potassium depletion also causes renal hypertrophy and predisposes to renal cyst formation, particularly when there is increased mineralocorticoid activity.

Acid-Base Metabolic alkalosis is a common acid-base consequence of potassium depletion and is due to increased renal net acid excretion.¹⁵ Conversely, metabolic alkalosis may increase renal potassium excretion, resulting in potassium depletion. Severe hypokalemia can lead to respiratory muscle weakness and the development of respiratory acidosis.

Polyuria Severe hypokalemia also impairs concentrating ability, causing mild polyuria, typically 2 to 3 liters per day. Both increased thirst and mild nephrogenic diabetes insipidus contribute to the polyuria.¹⁶

Hepatic Encephalopathy

Hypokalemia increases renal ammonia production, approximately half of which returns to the systemic circulation through the renal veins and may worsen hepatic encephalopathy.¹⁷

Etiology

Hypokalemia results typically from one of four causes: pseudohypokalemia, redistribution, extrarenal potassium loss, and renal potassium loss. Of course, multiple causes may coexist in an individual person.

Pseudohypokalemia

Pseudohypokalemia refers to the condition in which serum potassium decreases, artifactually, after phlebotomy. The most common cause is acute myeloblastic leukemia, in which the large numbers of abnormal leukocytes take up potassium when the blood is stored in a collection vial for prolonged periods at room temperature. Rapid separation of plasma and storage at 4°C confirm this diagnosis and should be used for subsequent testing once pseudohypokalemia is diagnosed to avoid this artifact, leading to inappropriate treatment.

Redistribution

Because more than 98% of total body potassium is intracellular, small potassium shifts from the extracellular to the intracellular compartment can result in hypokalemia. As discussed before,

many hormones, particularly insulin, aldosterone, and β_2 -adrenergic agonists, stimulate transcellular potassium uptake.

Rarely, hypokalemia is due to hypokalemic periodic paralysis.¹⁸ In this condition, attacks occur generally during the night or the early morning or after a carbohydrate-rich meal. Flaccid paralysis that persists typically for 6 to 24 hours characterizes these attacks. A genetic defect in a dihydropyridine-sensitive calcium channel has been identified in some cases¹⁹; other cases are associated with hyperthyroidism.

Nonrenal Potassium Loss

The skin and the gastrointestinal tract normally excrete small amounts of potassium. On occasion, excessive sweating or chronic diarrhea causes substantial potassium loss.²⁰ Vomiting or nasogastric suction may also result in loss of potassium, although gastric fluids typically contain only 5 to 8 mmol/l of potassium. However, the concomitant metabolic alkalosis and the intravascular volume depletion result in secondary hyperaldosteronism that can increase urinary potassium loss and contribute to the development of hypokalemia.²⁰

Renal Potassium Loss

The most common cause of hypokalemia is renal potassium loss. This can occur from medications, endogenous hormone production, or, in rare conditions, intrinsic renal defects.

Medicines Both thiazide and loop diuretics increase urinary potassium excretion, and the incidence of diuretic-induced hypokalemia is both dose and treatment duration related. Adjusted for their natriuretic effect, thiazide diuretics cause more urinary potassium loss than loop diuretics do. Certain antibiotics increase urinary potassium excretion. Some penicillin analogues, such as carbenicillin, increase distal tubular delivery of a non-reabsorbable anion that obligates the presence of a cation such as potassium, thereby increasing urinary potassium excretion.²¹ The antifungal agent amphotericin directly increases collecting duct potassium secretion.²² Aminoglycosides may cause hypokalemia either with or without simultaneous nephrotoxicity. The mechanism is incompletely understood but may relate to magnesium depletion (see later discussion of magnesium sulfate). Cisplatin is a commonly used antineoplastic agent that can induce hypokalemia. Toluene exposure, from sniffing of certain glues, can also cause renal tubular acidosis with renal potassium wasting, leading to hypokalemia.²³ Finally, certain herbal products, including herbal cough mixtures, licorice tea, licorice root, and gan cao, contain glycyrrhizic and glycyrrhetic acids, which have mineralocorticoid-like effects.²⁴

Endogenous Hormones Endogenous hormones are important and common causes of hypokalemia. Aldosterone is the most important hormone regulating total body potassium homeostasis and causes hypokalemia both by stimulating potassium uptake into cells and by stimulating renal potassium excretion.

Other Rarely, genetic defects lead to excessive aldosterone production (see Chapter 47). In glucocorticoid-remediable aldosteronism, an adrenocorticotrophic hormone (ACTH)-regulated promoter is linked to the gene for aldosterone synthase, the rate-limiting enzyme for aldosterone synthesis.²⁵ As a result, aldosterone synthase expression is regulated by ACTH, and hyperaldosteronism ensues. In congenital adrenal hyperplasia, there is persistent adrenal synthesis of 11-deoxycorticosterone, a potent mineralocorticoid.²⁶ This condition can be recognized by the associated effects on sex steroid production.

In another rare condition, glucocorticoid hormones activate the mineralocorticoid receptor. Under normal conditions, the enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) rapidly metabolizes cortisol to cortisone, thereby preventing inappropriate activation of mineralocorticoid receptors.²⁷ If this does not occur, glucocorticoid hormones are able to activate mineralocorticoid receptors. Some compounds, such as glycyrrhetic acid, found in some chewing tobacco and licorice preparations, inhibit 11 β -HSD, allowing cortisol to exert mineralocorticoid-like effects.²⁸ In severe Cushing's syndrome, circulating cortisol exceeds the metabolic capacity of 11 β -HSDH and can cause hypokalemia.²⁹ Genetic deficiency of 11 β -HSD (type 2) is rare but leads to severe hypertension and hypokalemia.

Magnesium Depletion

Magnesium deficiency inhibits renal potassium retention.³⁰ This is particularly true with diuretic-induced hypokalemia and in certain cases of aminoglycoside- and cisplatin-induced potassium wasting. This condition should be suspected in the individual in whom potassium replacement does not correct the hypokalemia.

Intrinsic Renal Defect

Intrinsic renal potassium transport defects leading to hypokalemia are rare but have led to important advances in our understanding of renal solute transport. Patients with Bartter syndrome have hypokalemia, reduced or normal blood pressure, hyperreninemia, metabolic alkalosis, and hypercalciuria. They typically present at a young age with severe volume depletion and growth retardation. Bartter syndrome results from genetic abnormalities in proteins involved in thick ascending limb of the loop of Henle sodium and potassium transport.³¹ Gitelman's syndrome is similar to Bartter syndrome, except that patients have hypocalciuria, have milder clinical manifestations, and usually are diagnosed later in life. Gitelman's syndrome results from genetic abnormalities in the proteins involved in distal convoluted tubule sodium and potassium transport and causes clinical abnormalities similar to those seen with excessive thiazide diuretic use.³²

Liddle syndrome is characterized by severe hypertension, hypokalemia, and suppressed renin and aldosterone levels. This condition is due to a mutation resulting in activation of the collecting duct epithelial sodium channel, leading to excessive sodium reabsorption, potassium excretion, volume expansion, and hypertension.³³

Bicarbonaturia

Bicarbonaturia can result from metabolic alkalosis, distal renal tubular acidosis, or treatment of proximal renal tubular acidosis. In each case, the increased distal tubular bicarbonate delivery increases potassium secretion.

Diagnosis

The evaluation of hypokalemia is summarized in Figure 9.6. One should first exclude pseudohypokalemia or redistribution from the extracellular to the intracellular space. Insulin, aldosterone or its synthetic analogue fludrocortisone, and sympathomimetic agents, such as theophylline and β_2 -adrenergic receptor agonists, are common causes of potassium redistribution.

If neither of these possibilities is present, the hypokalemia probably represents total body potassium depletion due to renal,

gastrointestinal, or skin losses. Renal potassium loss is most frequently due to diuretics or metabolic alkalosis. Hypomagnesemia-induced hypokalemia causes renal potassium wasting and is frequently a complication of diuretic use. Rarer causes of renal potassium loss include renal tubular acidosis, diabetic ketoacidosis, and ureterosigmoidostomy. Primary aldosteronism, surreptitious diuretic use or vomiting, concomitant magnesium depletion, and Bartter or Gitelman's syndrome should be considered when the cause of the hypokalemia is not obvious. Finally, excessive potassium loss may result through the skin (excessive sweating) or from diarrhea, vomiting, nasogastric suction, or a gastrointestinal fistula. Patients are occasionally reluctant to admit to self-induced diarrhea, and the diagnosis may need to be confirmed by sigmoidoscopy or direct testing of the stool for cathartic agents.

Treatment

The risks associated with hypokalemia must be balanced against the risks of therapy. Usually, the primary short-term risks are cardiovascular arrhythmias and neuromuscular symptoms. In contrast, the primary risk of overaggressive replacement is acute hyperkalemia, which can cause ventricular fibrillation and sudden death.

Conditions requiring urgent therapy are rare. The clearest indications are hypokalemic periodic paralysis, severe hypokalemia in a patient requiring urgent surgery, and acute myocardial infarction in the patient with significant ventricular ectopy. In such cases, KCl can be given intravenously at a dose of 5 to 10 mmol during 15 to 20 minutes. This dose can be repeated as needed. Close, continuous monitoring of the serum potassium concentration and the electrocardiogram (ECG) is necessary to reduce the risk of hyperkalemia.

The body responds to chronic hypokalemia due to potassium losses by shifting potassium from the intracellular to the extracellular space. This minimizes the apparent magnitude of the hypokalemia, and the amount of potassium needed to replace the deficit is much greater than predicted by the change in extracellular potassium concentration and the extracellular fluid volume (Fig. 9.7). Potassium replacement can be given intravenously or orally, which is preferred if the patient can take oral medication and there is normal gastrointestinal tract function. When it is administered intravenously, replacement can be given safely at a rate of 10 mmol KCl per hour. Although significant variations can occur between patients, intravenous administration of 20 mmol KCl typically increases the serum potassium by ~0.25 mmol/L.³⁴ If more rapid replacement is necessary, 20 mmol/h can be administered through a central venous catheter, but simultaneous continuous ECG monitoring should be used under these circumstances.

The parenteral fluids used for potassium administration can affect the response. In patients without diabetes mellitus, dextrose administration increases serum insulin levels, which can cause redistribution of potassium from the extracellular to the intracellular space. As a result, if KCl is administered in dextrose-containing solutions (e.g., 5% dextrose in water), the dextrose load may actually stimulate cellular potassium uptake to an extent that exceeds the KCl replacement rate, resulting, paradoxically, in worsening of the hypokalemia.³⁵ Consequently, parenteral KCl should be administered in dextrose-free solutions.

The risk of hyperkalemia due to potassium replacement is less when it is given orally. This reflects several factors, most prominently gut sensors that minimize changes in serum potassium levels.

Figure 9.6 Diagnostic evaluation of hypokalemia. BP, blood pressure; GI, gastrointestinal; GRA, glucocorticoid-remediable aldosteronism; RTA, renal tubular acidosis.

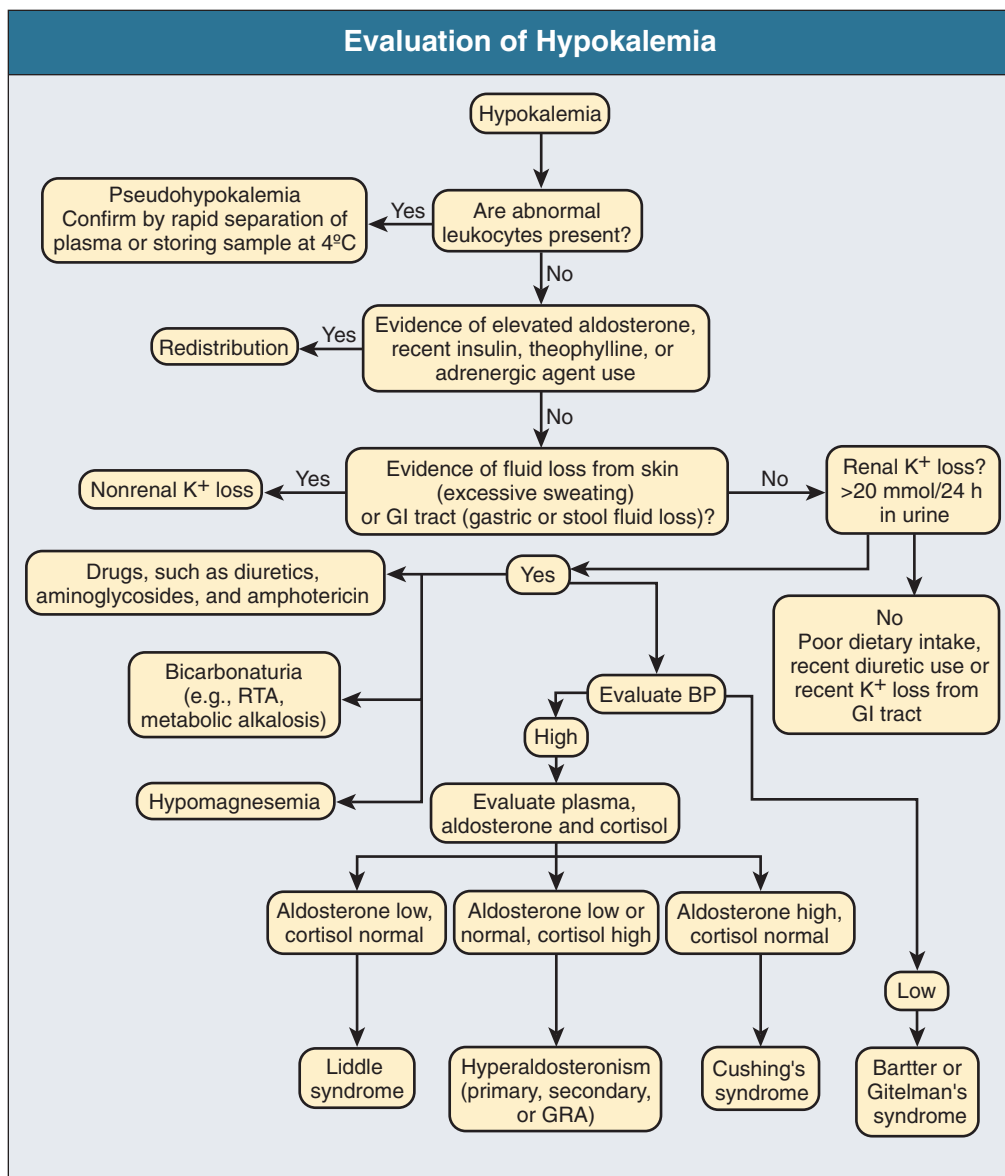

Figure 9.7 Total body potassium deficit in hypokalemia. Because of shift of potassium from the intracellular to the extracellular fluid compartment during chronic potassium depletion, the magnitude of deficiency can be masked. It is generally much larger than would be calculated solely from the change in plasma potassium and the extracellular fluid volume.

The underlying condition should be treated whenever possible. If patients with diuretic-induced hypokalemia still need diuretics, concomitant use of potassium-sparing diuretics may be considered. When oral replacement therapy is required, KCl is the preferred drug in all patients, except those with metabolic acidosis, in which potassium bicarbonate or potassium citrate may be considered a concomitant alkali source. If indicated for other reasons, β -blockers, ACE inhibitors, and ARBs can assist in maintaining serum potassium levels.

Hypomagnesemia can lead to refractoriness to potassium replacement because of inability of the kidneys to decrease potassium excretion.³⁰ Correction of the hypokalemia may not occur until the hypomagnesemia is corrected. Patients with unexplained hypokalemia or with diuretic-induced hypokalemia should have serum magnesium checked and, if indicated, magnesium replacement therapy instituted, usually with MgSO_4 , and periodic measurement of serum $[\text{Mg}^{2+}]$.

HYPERKALEMIA

Epidemiology

Hyperkalemia develops in less than 1% of normal healthy adults in the absence of significant underlying disease or medication use. This low frequency is a testament to the potent mechanisms for renal potassium excretion. Accordingly, hyperkalemia should suggest an underlying impairment of renal potassium excretion. Rarely, pseudohyperkalemia or conditions that shift potassium from the intracellular space to the extracellular space are present.

Clinical Manifestations

Hyperkalemia may be asymptomatic but still life-threatening. The most prominent effect of hyperkalemia is alteration of cardiac conduction. This is demonstrable on the ECG (Fig. 9.8). The initial effect of hyperkalemia is a generalized increase in the height of the T waves, most evident in the precordial leads, which is known as tenting. More severe hyperkalemia is associated with delayed electrical conduction, resulting in increased PR and QRS intervals. This is followed by progressive flattening and eventual absence of the P waves. Under extreme conditions, the QRS complex widens sufficiently that it merges with the T wave, resulting in a sine wave pattern. Finally, an idioventricular rhythm followed by ventricular fibrillation develops. Although the ECG findings correlate generally with the degree of hyperkalemia, the rate of progression from mild to severe cardiac effects may be unpredictable and may not correlate well with changes in the plasma potassium concentration.

Hyperkalemia also affects muscle contraction. Skeletal muscle cells are particularly sensitive to hyperkalemia, causing weakness ("rubbery" or "spaghetti" legs). With severe hyperkalemia, respiratory failure may occur from paralysis of the diaphragm.

Etiology

Hyperkalemia can be due to pseudohyperkalemia, redistribution of potassium from the intracellular to the extracellular space, or imbalances between potassium intake and renal potassium excretion. A diagnostic approach is shown in Figure 9.9.

Pseudohyperkalemia

Serum potassium concentration may be artificially increased (pseudohyperkalemia) because of potassium release from eryth-

Figure 9.8 Electrocardiographic changes in hyperkalemia. Progressive hyperkalemia results in identifiable changes on the ECG. These include peaking of the T wave, flattening of the P wave, prolongation of the PR interval, ST-segment depression, prolongation of the QRS complex, and, eventually, progression to a sine wave pattern. Ventricular fibrillation may occur at any time during this progression.

rocyte hemolysis during collection or from cellular elements during clotting. The latter most commonly occurs in people with severe leukocytosis ($>70,000/\text{cm}^3$) or marked thrombocytosis. Approximately one third of patients with platelet counts of 500 to $1000 \times 10^9/\text{l}$ exhibit pseudohyperkalemia. Ischemia from prolonged tourniquet time or exercise of the limb in the presence of a tourniquet can also lead to abnormally increased potassium values. Pseudohyperkalemia may also occur with hemolysis, which occurs in patients with rheumatoid arthritis or infectious mononucleosis, as well as in families that have abnormal red blood cell membrane potassium permeability.

Pseudohyperkalemia is diagnosed by showing that the serum potassium concentration is more than 0.3 mmol/l higher than in a simultaneous plasma sample. Once it is diagnosed, all further potassium levels should be measured in plasma to avoid inappropriate treatment.

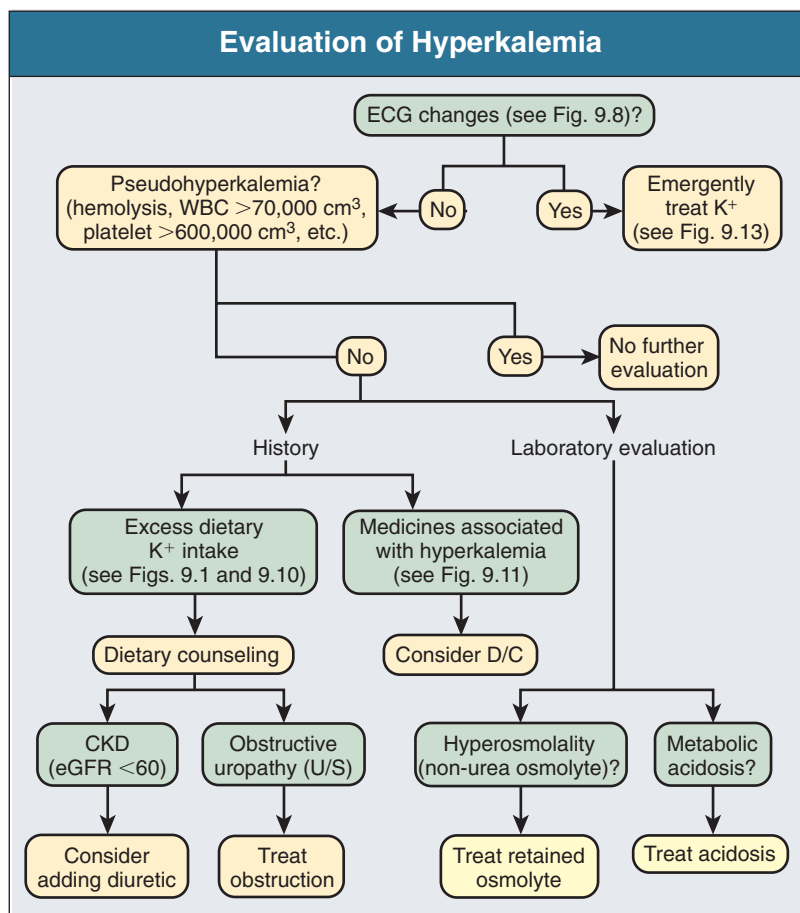

Redistribution

Hyperkalemia may be observed in cases of severe hyperglycemia (due to effects of osmolarity), in association with severe nonorganic acidosis, and rarely with β -blockers. Patients who have received mannitol may also develop hyperosmolarity-induced hyperkalemia.

Excess Intake

Excessive potassium ingestion generally does not lead to hyperkalemia unless other contributing factors are present. Under normal conditions, the kidney can excrete hundreds of millimoles of potassium daily. However, if renal potassium excretion is impaired, for example, by drugs or renal impairment, excessive potassium intake can produce hyperkalemia.

Common causes of excess potassium intake are potassium supplements, salt substitutes, enteral nutrition products, and

Figure 9.9 Evaluation of hyperkalemia.**Potassium Content of Common Enteral Products**

	Calories/ml	Potassium (mmol/l)	Sodium (mmol/l)	Osmolality (mOsm/kg)

Figure 9.10 Potassium content of common enteral products.

common foods. As many as 4% of patients receiving potassium supplements develop hyperkalemia. Typical salt substitutes contain 10 to 13 mmol potassium/g, or 283 mmol/tablespoon. Many enteral nutrition products contain 40 mmol/l KCl or more; administration of 100 ml/h of such products can result in a potassium intake of ~100 mmol/day. **Figure 9.10** summarizes the potassium content of many common enteral products. Finally, many food products are particularly high in potassium (see **Fig. 9.1**), and many pharmacies routinely label diuretic medicine bottles with suggestions for the patient to increase potassium intake from dietary sources, such as bananas and fresh

fruits. **Figure 9.1** summarizes the potassium content of some common foods.

Impaired Renal Potassium Secretion

The normal kidney possesses a remarkable ability to excrete potassium, so chronic hyperkalemia is difficult to produce unless renal potassium secretion is impaired. Factors that affect renal potassium excretion are classified into those due to reduced nephron number and those due to intrinsic impairment of renal potassium handling.

Because the kidney is the primary organ regulating potassium excretion, impaired renal function decreases maximal potassium excretion. In the absence of other contributing factors, renal potassium excretion is moderately well preserved until GFR is reduced to 10 to 20 ml/min. However, both CKD and acute kidney injury (AKI) limit maximal renal potassium excretion. This factor may be particularly important to consider in patients who are elderly, are cachectic, or have limb amputations, in whom low serum creatinine concentration leads to underestimation of the degree of renal impairment.

Obstructive uropathy leads frequently to hyperkalemia.³⁶ At least in part, it appears to be due to decreased Na⁺,K⁺-ATPase expression and activity.³⁷ In many cases, the hyperkalemia may persist for weeks after relief of the obstruction.

Specific Medicines The renin-angiotensin-aldosterone axis is the primary hormonal system regulating renal potassium excretion. Accordingly, medications that interfere with this system or that inhibit the cellular mechanisms of renal potassium

Medications Associated with Hyperkalemia		
Class	Mechanism	Example
Potassium-containing medicines	Increased potassium intake	KCl, PCN G, PolyCitra, PolyCitra K
β-Adrenergic receptor blockers	Inhibit renin release	Propranolol, metoprolol, atenolol
ACE inhibitor	Inhibit conversion of angiotensin I to Ang II	Captopril, lisinopril
Angiotensin receptor blocker (ARB)	Inhibit activation of AT ₁ receptor by Ang II	Losartan, valsartan, irbesartan
Heparin	Inhibit aldosterone synthase, rate-limiting enzyme for aldosterone synthesis	Heparin sodium
Aldosterone receptor antagonist	Block aldosterone receptor activation	Spironolactone, eplerenone
Potassium-sparing diuretic	Block collecting duct apical sodium channel, decreasing gradient for potassium secretion	Amiloride, triamterene; certain antibiotics, specifically trimethoprim and pentamidine
NSAID and COX-2 inhibitors	Inhibit prostaglandin stimulation of collecting duct potassium secretion; inhibit renin release	Ibuprofen
Digitalis glycosides	Inhibit Na ⁺ , K ⁺ -ATPase necessary for collecting duct potassium secretion	Digoxin
Calcineurin inhibitors	Inhibit Na ⁺ , K ⁺ -ATPase necessary for collecting duct potassium secretion	Cyclosporine, tacrolimus

Figure 9.11 Medications associated with hyperkalemia. Ang II, angiotensin II.

Transtubular Potassium Gradient		
TTKG is a measurement of net K ⁺ secretion by the distal nephron after correcting for changes in urinary osmolality and is often used to determine whether hyperkalemia is caused by aldosterone deficiency/resistance or whether the hyperkalemia is secondary to nonrenal causes. $TTKG = (K_u/K_s) \times (S_{osm}/U_{osm})$, where K_u and K_s are the concentration of K ⁺ in urine and serum, respectively, and U_{osm} and S_{osm} are the osmolalities of urine and serum, respectively.		
TTKG Value	Indication	
6–12	Normal	
>10	Suggests normal aldosterone action and an extrarenal cause of hyperkalemia	
<5–7	Suggests aldosterone deficiency or resistance	
After 0.05 mg 9α-fludrocortisone	<div> <div>>10</div> <div>Hypoaldosteronism is likely</div> </div> <div> <div>No change</div> <div>Suggests a renal tubule defect from either K⁺-sparing diuretics (amiloride, triamterene, spironolactone), aldosterone resistance (interstitial renal disease, sickle cell disease, urinary tract obstruction, pseudohypoaldosteronism type 1), or increased distal K⁺ reabsorption (pseudohypoaldosteronism type 2, urinary tract obstruction)</div> </div>	

Figure 9.12 Transtubular potassium gradient (TTKG).

excretion are frequent causes of hyperkalemia. Classes of medications that inhibit potassium secretion and their mechanism of action are summarized in Figure 9.11.

Intrinsic Renal Defect The rare genetic disorder pseudohypoaldosteronism type 2, also known as Gordon's syndrome, is characterized by hypertension, hyperkalemia, non-anion gap metabolic acidosis, and normal GFR.³⁸ Mutations in either of two proteins, WNK1 or WNK4, increase sodium absorption and inhibit potassium secretion in the distal convoluted tubule and collecting duct and lead to this phenotype.^{8,39}

Distinguishing Renal and Nonrenal Mechanisms of Hyperkalemia

In most circumstances, a careful history and a 24-hour urine K⁺ excretion rate will distinguish renal (K⁺ <20 mmol/day) from extrarenal (K⁺ >40 mmol/day) causes of hyperkalemia. Furthermore, in patients with a low urinary K⁺ level, the administration

of fludrocortisone may be used to distinguish aldosterone deficiency (urine K⁺ increases to >40 mmol/day) from aldosterone resistance (K⁺ remains <20 mmol/day). However, urinary K⁺ measurements may be difficult to interpret because K⁺ excretion is dependent on multiple factors; the most important are GFR, tubule lumen flow, and water reabsorption in the distal tubule and collecting duct. Fractional excretion of K⁺ may help in differentiating renal from nonrenal causes of hyperkalemia because it normalizes K⁺ excretion relative to GFR. When urine K⁺ is equivocal, the transtubular K⁺ gradient may be informative (Fig. 9.12).

Treatment

Therapies for hyperkalemia are divided into those that minimize the cardiac effects of hyperkalemia; those that induce potassium uptake by cells, resulting in a decrease in plasma potassium; and those that remove potassium from the body. Figure 9.13

Treatment of Hyperkalemia				
Mechanism	Therapy	Dose	Onset	Duration
Antagonize membrane effects	Calcium	Calcium gluconate, 10% solution, 10 ml IV over 10 min	1–3 min	30–60 min
Cellular potassium uptake	Insulin	Regular insulin, 10 U IV, with dextrose, 50%, 50 ml if plasma glucose <250 mg/dl	30 min	4–6 h
	β_2 -Adrenergic agonist	Nebulized albuterol, 10 mg	30 min	2–4 h
Potassium removal	Sodium polystyrene sulfonate	Kayexalate, 60 g PO, in 20% sorbitol, or 60 g in 250 ml water, per retention enema	1–2 h	4–6 h
	Hemodialysis	—	Immediate	Until dialysis completed

Figure 9.13 Treatment of hyperkalemia.

summarizes the available treatments, their mechanism of action, time at onset of action, and duration of action.

Treatment of hyperkalemia should not include NaHCO_3 therapy unless the patient is frankly acidotic ($\text{pH} < 7.2$) or unless substantial endogenous renal function is present. Administration of hypertonic NaHCO_3 can cause additional volume overload (a frequent issue in the patient with oliguric AKI), can cause acute hyponatremia, and, in general, has little effect on serum potassium concentration.⁴⁰

Blocking Cardiac Effects

Intravenous calcium administration specifically antagonizes the effects of hyperkalemia on the myocardial conduction system and myocardial repolarization. Calcium is the most rapid way to stabilize the membrane voltage and to treat hyperkalemia; it should be given by the intravenous route if unambiguous ECG changes of hyperkalemia are present. All patients with prolonged PR interval, widened QRS complexes, or absence of P waves should receive intravenous calcium without delay. Responses can occur within 1 to 3 minutes and may last for 30 to 60 minutes. The dose may be repeated as needed if ECG changes persist or recur. If a delay in the institution of dialysis is anticipated, a calcium infusion should be considered because the effect of a calcium bolus is transient.

Intravenous calcium should not be administered in NaHCO_3 -containing solutions because CaCO_3 precipitation can occur. Hypercalcemia, which occurs during rapid calcium infusion, can potentiate the myocardial toxicity of digoxin; patients taking digoxin, particularly if they have evidence of digoxin toxicity as a contributing cause of hyperkalemia, should be given calcium as a slow infusion lasting 20 to 30 minutes.

Cellular Potassium Uptake

The second most rapid way to treat hyperkalemia is to stimulate cellular potassium uptake, with either insulin or β_2 -adrenergic agonist administration. Insulin rapidly stimulates cellular potassium uptake and should be administered intravenously to ensure predictable bioavailability. Effects on serum potassium concentration are generally seen within 10 to 20 minutes and will last for 4 to 6 hours. Glucose is generally coadministered to avoid hypoglycemia but may not be needed if hyperglycemia coexists, particularly because extracellular glucose in patients with diabetes mellitus can function as an “ineffective osmole” and can increase serum potassium concentration. If a delay in dialysis is anticipated, administration of a continuous infusion of insulin (4 to 10 U/h) with D_{10}W (10% dextrose in water) may be beneficial;

periodic monitoring of serum glucose and potassium concentrations is required.

β_2 -Adrenergic receptor agonists directly stimulate cellular potassium uptake. These can be given through the intravenous, inhaled, or subcutaneous route. However, β_2 -agonist therapy frequently induces substantial tachycardia, and as many as 25% of patients do not respond when it is given by nebulizer.⁴¹ A frequent mistake in administering nebulized β_2 -adrenergic receptor agonists is underdosage; the dose required is 2 to 8 times that usually given by nebulizer for bronchodilation and 50 to 100 times greater than the dose administered by metered dose inhalers.

Potassium Removal

Most cases of severe hyperkalemia are associated with increased extracellular fluid potassium content. Definitive treatment of these patients requires removal of potassium from the extracellular fluid.

In selected cases, treatment that focuses on increasing renal potassium elimination may be adequate. With chronic or mild hyperkalemia, loop or thiazide diuretics increase renal potassium excretion; loop diuretics may be the therapy of choice for patients with hyperkalemic renal tubular acidosis.⁴² With life-threatening hyperkalemia, diuretics should be avoided because the rate of renal potassium excretion usually will not be adequate, and most patients will have renal impairment, which decreases the response to diuretic therapy. Whereas synthetic mineralocorticoids, such as fludrocortisone, increase renal potassium excretion, a relative contraindication to their use is the accompanying renal sodium retention, intravascular volume expansion, and increased blood pressure. Furthermore, mineralocorticoids can increase the rate of progression of CKD. If a rapidly reversible cause of renal failure is identified, such as obstructive uropathy or prerenal failure from volume depletion, treatment of the underlying condition along with close observation of plasma potassium concentration and continuous ECG observation may be adequate.

A second mode of potassium elimination is with cation exchange resins, such as sodium polystyrene sulfonate (Kayexalate). This resin exchanges sodium for potassium in the gastrointestinal tract, enabling potassium elimination. It can be administered either orally or per rectum as a retention enema. The rate of potassium removal is relatively slow, requiring about 4 hours for full effect, although administration as a retention enema results in more rapid onset of action. When it is given orally, sodium polystyrene sulfonate is generally administered with 20% sorbitol to avoid constipation. If it is given as an enema, sorbitol should be avoided because rectal administration

of sodium polystyrene sulfonate with sorbitol can cause colonic perforation.⁴³

Acute hemodialysis is the primary method of potassium removal when renal function is absent and hyperkalemia is persistent or severe. Serum potassium can decrease as much as 1.2 to 1.5 mmol/h with a potassium-free dialysate. In general, the more severe the hyperkalemia, the more rapid should be the reduction in plasma potassium and the lower the dialysate potassium concentration. However, care should be taken to avoid rapidly reducing the plasma potassium concentration in patients with ischemic heart disease or those predisposed to arrhythmias. In these patients, dialysis for a longer period with dialysate potassium of 3 to 3.5 mmol/l is better because serum potassium concentration can equilibrate to these levels during the dialysis. Continuous dialysis modalities, such as peritoneal dialysis and chronic venovenous hemodialysis, generally do not remove potassium sufficiently quickly for use in life-threatening hyperkalemia.

If dialysis is delayed, for example, because access to equipment or nursing support is not immediate or while vascular access is established, other therapies should be instituted and continued until hemodialysis is begun.

Specific therapies are available for certain causes of hyperkalemia. For example, digoxin-specific Fab fragments are beneficial in cases of severe digitalis toxicity.⁴⁴ Patients with acute urinary tract obstruction and hyperkalemia may be treated with relief of the urinary tract obstruction, but the rate of potassium excretion after relief of obstruction is variable, and frequent measurement of serum potassium concentration is necessary.

Disorders of Calcium, Phosphate, and Magnesium Metabolism

Bryan Kestenbaum, Tilman B. Drüeke

HOMEOSTASIS OF CALCIUM AND DISORDERS OF CALCIUM METABOLISM

Distribution of Calcium in the Organism and Calcium Homeostasis

Most calcium is bound and associated with bone structures (99%). The majority of free calcium, either in diffusible (ultra-filterable) nonionized form or in ionized form (Ca^{2+}), is found in the intracellular and extracellular fluid compartments. There is a steep concentration gradient of Ca^{2+} between the intracellular and the extracellular milieu as shown in [Figure 10.1](#).

The plasma concentration of Ca^{2+} is tightly regulated by the actions of parathyroid hormone (PTH) and calcitriol (1,25-dihydroxycholecalciferol). The physiologic role of other calcium regulatory hormones, such as calcitonin, estrogens, and prolactin, is less clear. [Figures 10.2](#) and [10.3](#) demonstrate the physiologic defense mechanisms used to counter changes in serum Ca^{2+} levels. Serum Ca^{2+} levels are also influenced by acid-base status; alkalosis causes a decrease in Ca^{2+} , and acidosis has the opposite effect.

Long-term maintenance of calcium homeostasis depends on the adaptation of intestinal Ca^{2+} absorption to the needs of the organism, on the balance between bone accretion and resorption, and on urinary excretion of calcium (see [Fig. 10.3](#)).

Intestinal, Skeletal, and Renal Handling of Calcium

Gastrointestinal calcium absorption is a selective process; only about 25% of total dietary calcium is absorbed. Ca^{2+} transport across the intestinal wall occurs in two directions: absorption and secretion. Absorption can be subdivided into transcellular and paracellular flow ([Fig. 10.4](#)).¹ Transcellular calcium flux takes place through the recently identified TRPV6 calcium channel. Calcitriol is its most important hormonal regulatory factor.² After binding to and activating the vitamin D receptor (VDR), calcitriol increases active transport by inducing the expression of TRPV6, calbindin D_{9k} , and Ca^{2+} -ATPase (PMCA1b) (see [Fig. 10.4](#)).³ Other hormones, including estrogens, prolactin, growth hormone, and PTH, also stimulate Ca^{2+} absorption, either directly or indirectly. The amount of dietary calcium intake also regulates the proportion of calcium absorbed through the gastrointestinal tract ([Fig. 10.5](#)).

Cutaneous synthesis on exposure to UV light converts 7-dehydrocholesterol to vitamin D substrate (cholecalciferol). Cholecalciferol has minimal inherent biologic activity and requires two hydroxylation steps for full hormonal activity. 25-Hydroxylation occurs in the liver, is thought to be non-rate-limiting, and is widely accepted as a summary measure of vitamin

D stores. Further hydroxylation to 1,25-dihydroxyvitamin D (calcitriol) occurs predominantly in the kidney, but also occurs in non-renal tissues.

Increased calcium absorption is required in puberty, pregnancy, and lactation. In all these states, calcitriol synthesis is increased. Intestinal Ca^{2+} absorption is also increased in vitamin D excess and acromegaly. Rarely, the ingestion of calcium and alkali in large quantities can overwhelm gastrointestinal checks on calcium absorption, resulting in hypercalcemia (milk-alkali syndrome); however, innate limitations on gastrointestinal calcium absorption prevent this condition from occurring in most individuals. A decrease in intestinal Ca^{2+} transport occurs in a low Ca^{2+} /phosphate ratio in the food, a high vegetable fiber and fat content of the diet, corticosteroid treatment, estrogen deficiency, advanced age, gastrectomy, intestinal malabsorption syndromes, diabetes mellitus, and renal failure. The decrease in Ca^{2+} absorption in the elderly probably results from multiple factors in addition to lower serum calcitriol and intestinal VDR levels.⁴

The net balance between Ca^{2+} entry and exit fluxes is positive during skeletal growth in children, zero in young adults, and negative in the elderly. Exchangeable skeletal Ca^{2+} contributes to maintenance of extracellular Ca^{2+} homeostasis. Several growth factors, hormones, and genetic factors participate in the differentiation from the mesenchymal precursor cell to the osteoblast and the maturation of the osteoclast from its granulocyte-macrophage precursor cell ([Fig. 10.6](#)). The regulation of bone formation and resorption involves a large number of hormones, growth factors, and mechanical factors ([Fig. 10.7](#)).⁵

The kidneys play a major role in the minute-by-minute regulation; the intestine and the skeleton ensure homeostasis in the mid and long term. To perform its task, the kidney uses a complex system of filtration and reabsorption ([Fig. 10.8](#)). The adjustment of blood Ca^{2+} is mainly achieved by modulation of tubular Ca^{2+} reabsorption in response to the body's needs, perfectly compensating minor increases or decreases in the filtered load of calcium at the glomerular level, which is normally about 220 mmol (8800 mg) in 24 hours (see [Fig. 10.3](#)). In the proximal tubule, most of the Ca^{2+} is reabsorbed by convective flow (as for Na^{+} and water); in the distal segments of the tubule, the transport mechanisms are more complex. States of excess volume delivery to the kidney, such as a high-sodium diet, diminish the concentration gradient between proximal tubule and peritubular capillary, reducing calcium absorption and increasing calcium in the urine. This mechanism is thought to play a role in the pathogenesis of calcium-based kidney stones. On the other hand, volume depletion states increase salt, water, and (by convection) calcium reabsorption in the proximal tubule, exacerbating states of hypercalcemia. In the thick ascending loop, the transport of Ca^{2+} is primarily passive by the paracellular route, depending on the

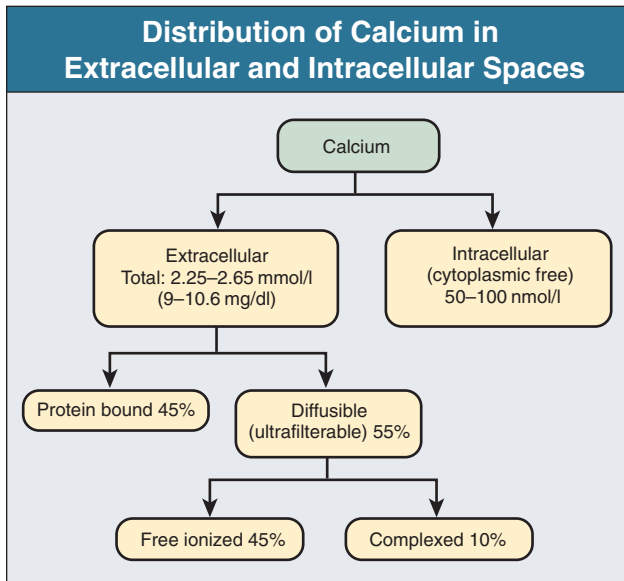

Figure 10.1 Distribution of calcium in extracellular and intracellular spaces.

electrical gradient, with the tubular lumen being positive, and also on the presence of claudin 16 in the tight junction. At this step, Ca^{2+} transport is enhanced by PTH, probably through an increase in paracellular permeability, but it is reduced by an increase in extracellular Ca^{2+} involving the Ca^{2+} -sensing receptor (CaR_G). Specifically, stimulation of CaR_G by elevated serum calcium levels decreases the activity of rectifying K^+ channels (ROMK), resulting in less $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter activity and less calcium reabsorption in this segment. In the distal tubule, Ca^{2+} transport is primarily active by the transcellular route, through TRPV5 located in the apical membrane and coupled with a specific basolateral $\text{Ca}^{2+}\text{-ATPase}$ (PMCA1b) and a $\text{Na}^+\text{-Ca}^{2+}$ exchanger (NCX1). Both PTH and calcitriol regulate distal tubular transport.

Numerous factors control the glomerular filtration and tubular reabsorption of Ca^{2+} .^{3,6,7} Elevated renal blood flow and glomerular filtration pressure (during extracellular fluid volume expansion) lead to an increase in filtered load, as do changes in the ultrafiltration coefficient K_f and an increase in glomerular surface. True hypercalcemia also increases ultrafilterable calcium, whereas true hypocalcemia decreases it. PTH decreases glomerular K_f and thus reduces the ultrafiltered calcium load; it also increases Ca^{2+} reabsorption in the distal nephron. However, PTH and PTH-related peptide (PTHrP) also induce hypercalcemia, and because of the increase in serum calcium, the excretion of filtered calcium is elevated overall. Both extracellular Ca^{2+} and intracellular Ca^{2+} reduce tubular calcium reabsorption by activating CaR_G , and the effect of extracellular Ca^{2+} is enhanced by calcimimetics. Metabolic and respiratory acidoses lead to hypercalciuria, respiratory acidosis through an increase in plasma Ca^{2+} and metabolic acidosis through calcium release from bone and an inhibitory effect on tubular Ca^{2+} reabsorption. Conversely, alkali ingestion reduces renal excretion of calcium. The enhancing effect of phosphate depletion on urinary calcium elimination can partly occur through changes in PTH and calcitriol secretion. Dietary factors modify urinary excretion of calcium, mostly by their effects on intestinal Ca^{2+} absorption. Several classes of diuretics act directly on the tubules: loop

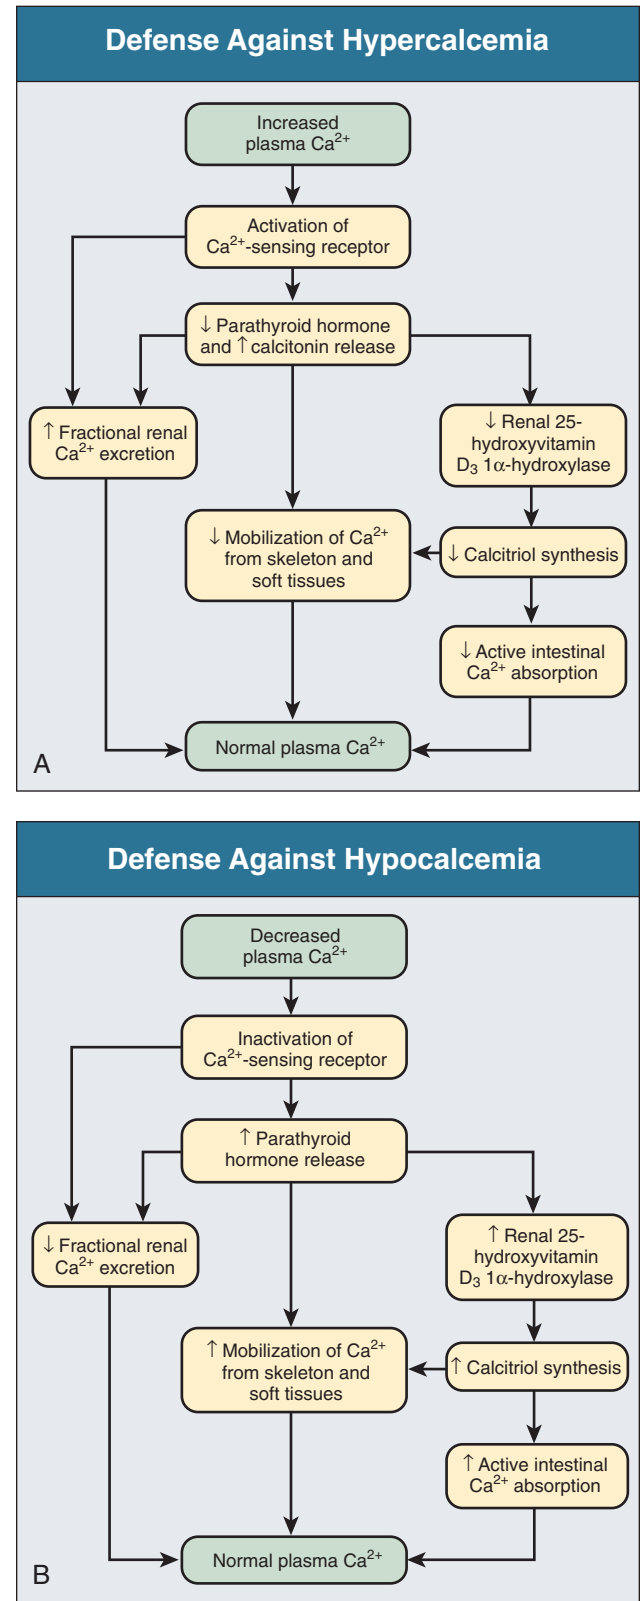

Figure 10.2 Physiologic defense mechanisms to counter changes in serum calcium. **A**, Hypercalcemia. **B**, Hypocalcemia. (Modified from reference 8.)

Figure 10.3 Calcium homeostasis in the healthy adult. Net zero Ca^{2+} balance is the result of net intestinal absorption (absorption minus secretion) and urinary excretion, which, by definition, are the same. After its passage into the extracellular fluid, Ca^{2+} enters the extracellular space, is deposited in bone, or is eliminated by the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude under steady-state conditions. Values linked to compartments represent absolute amounts of calcium whereas values linked to the intestine and the kidney represent daily calcium entries and exits, and values between organs and compartments represent daily fluxes.

Figure 10.4 Transepithelial calcium transport in the small intestine. Calcium penetrates into the enterocyte by a recently discovered calcium channel (TRPV6) through the brush border membrane along a favorable electrochemical gradient. Under physiologic conditions, the cation is pumped out of the cell at the basolateral side against a steep electrochemical gradient by the adenosine triphosphate-consuming pump Ca^{2+} -ATPase. When there is a major elevation of intracytoplasmic Ca^{2+} , the cation leaves the cell using the Na^{+} - Ca^{2+} exchanger. Passive Ca^{2+} influx and efflux are sensitive to calcitriol, which binds the vitamin D receptor (VDR).

diuretics and mannitol favor hypercalciuria, with a major impact on the thick ascending limb, whereas the thiazide diuretics and amiloride induce hypocalciuria.

HYPERCALCEMIA

Increased plasma total calcium concentration can result from an increase in plasma proteins (false hypercalcemia) or from an increase in plasma ionized Ca^{2+} (true hypercalcemia). Only the latter leads to clinically relevant hypercalcemia. When only the value for the total plasma calcium concentration is available rather than the free level ions, as is generally the case in clinical practice, plasma Ca^{2+} can be estimated by taking into account plasma albumin: an increase in albumin of 1.0 g/dl reflects a concomitant increase of 0.20 to 0.25 mmol/l (0.8 to 1.0 mg/dl) in plasma calcium. However, simple correction of total calcium for serum albumin may not be valid in patients with chronic kidney disease (CKD). A study of 691 individuals with CKD stages 3 to 5 demonstrated that the albumin-corrected total serum calcium concentration poorly correlated with the simultaneously measured ionized calcium concentration. Moreover, the two most common assays used to measure serum albumin yield discordant results in uremic patients, the bromocresol purple method providing lower albumin values than the bromocresol green method.

The recently cloned CaR_G has been identified in numerous tissues and its function well defined.¹² Mutations of the gene for CaR_G result in various clinical syndromes characterized either by hypercalcemia or by hypocalcemia (see later discussion). Several other Ca^{2+} receptors have been cloned subsequently. The precise functional properties of one of them, GPRC6A, which is

expressed in osteoblasts and clearly distinct from CaR_G , have been characterized.¹³ Its role in the regulation of osteoblast function and in human disease is still unknown.

Causes of Hypercalcemia

True hypercalcemia results from an increase in intestinal Ca^{2+} absorption, a stimulation of bone resorption, or a decrease in urinary Ca^{2+} excretion. Enhanced bone resorption is the predominant mechanism in most cases of hypercalcemia. The main causes of hypercalcemia are shown in Figure 10.9.

Malignant Neoplasias

The main cause of hypercalcemia is excessive bone resorption induced by neoplastic processes, usually solid tumors. Tumors of the breast, lung, and kidney are the most common, followed by hematopoietic neoplasias, particularly myeloma.

Most hypercalcemic tumors act on the skeleton either by direct invasion (metastases) or by producing factors that stimulate osteoclastic activity, including most commonly PTHrP as well as factors activating osteoclasts, transforming growth factors, prostaglandin E (PGE), rarely calcitriol and tumor necrosis factor α , and very rarely PTH, produced, for example, by parathyroid cancer.

Only 8 of the 13 first amino acids of PTHrP are identical with those of the N-terminal fragment of PTH, but the effects of both hormones on target cells are mostly the same. In addition to their common receptor, the PTH/PTHrP receptor, there is at least one other receptor, the PTH_2 receptor, which recognizes solely PTH, with similar or identical signal transduction systems. In pathologic conditions, most of the PTHrP in the body is

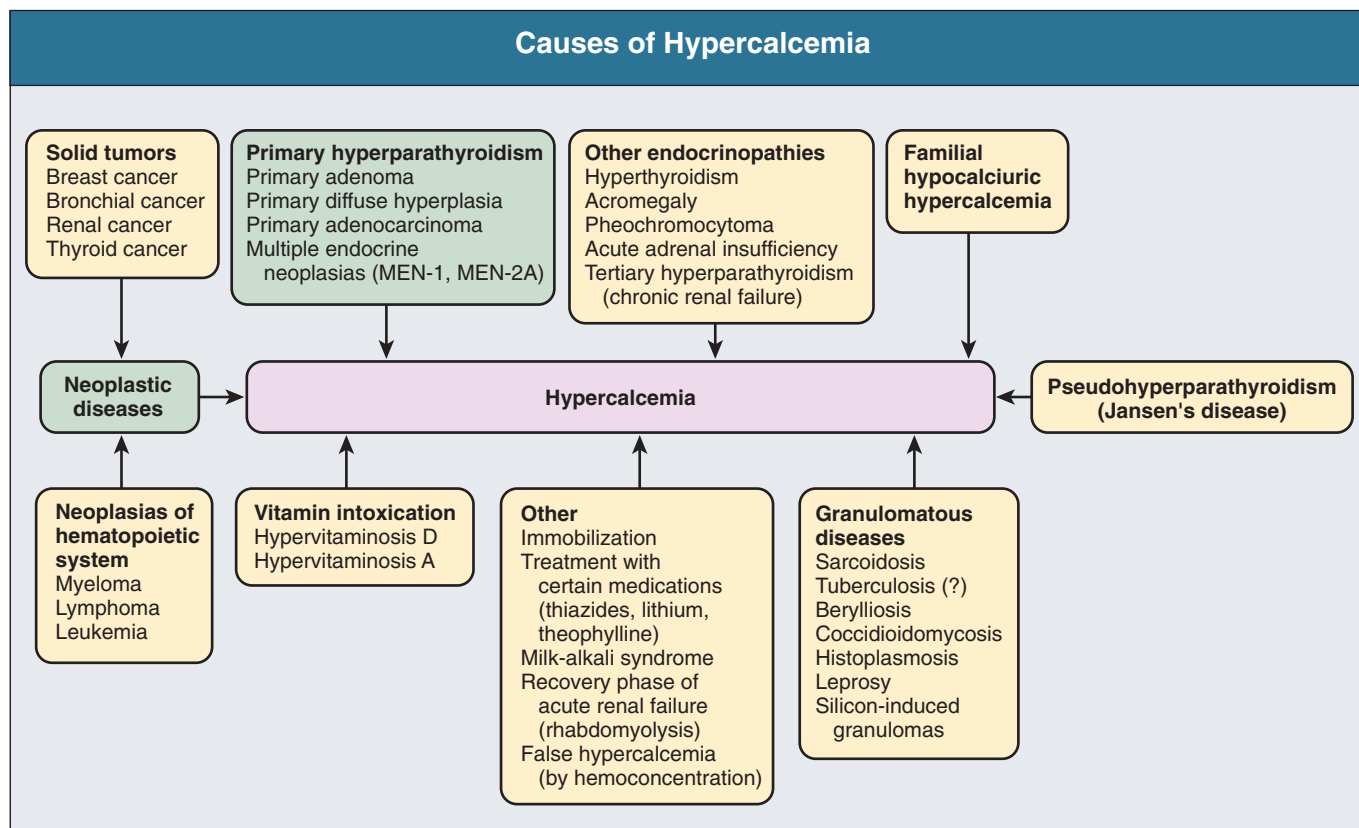

Figure 10.9 Causes of hypercalcemia. Green boxes indicate common causes of hypercalcemia. (From reference 11.)

synthesized by solid tumors. PTHrP stimulates osteoclastic activity and thus liberates excess quantities of calcium from the skeleton.

Osteoclast-activating factors secreted by myeloma plasmocytes and the lymphoblasts of malignant lymphomas include interleukins 1α , 1β , and 6 and also tumor necrosis factor α , which all stimulate osteoclast activity. Other osteoclast-activating factors are PGE_1 and PGE_2 , which can be secreted in large amounts by some tumors (especially renal tumors). Some lymphoid tumors synthesize excess quantities of calcitriol. This capacity has been described in Hodgkin's disease, T-cell lymphoma, and leiomyoblastoma.

Primary Hyperparathyroidism

The second most common cause of hypercalcemia is primary hyperparathyroidism. Early diagnosis is achieved through the widespread use of routine plasma calcium determination. In more than 80% of cases, the disease is caused by adenoma of a single parathyroid gland; in 10% to 15%, there is diffuse hyperplasia of all glands, and in less than 5%, a parathyroid cancer. Primary hyperparathyroidism can be inherited either as diffuse hyperplasia of the parathyroid glands alone or as a component in multiple glandular hereditary endocrine disorders. Patients with multiple endocrine neoplasia type 1 (MEN-1) have various combinations of parathyroid, anterior pituitary, enteropancreatic, and other endocrine tumors, resulting in hypersecretion of prolactin and gastrin in addition to PTH. This disease is caused by inactivating germline mutations of a tumor-suppressor gene (the *MEN-1* gene) that is inherited as an autosomal dominant trait. In MEN-2A, the thyroid medulla and the adrenal medulla are involved with the parathyroid, resulting in hypersecretion of calcitonin and catecholamines. This disease is caused by activating mutations of the *RET* proto-oncogene. It is also inherited as an autosomal dominant trait. Not all patients with mildly elevated plasma PTH levels develop hypercalcemia; the development of hypercalcemia may depend on a concomitant elevation of plasma calcitriol.

Jansen's Disease

Jansen's disease is a rare hereditary form of short-limbed dwarfism characterized by severe hypercalcemia, hypophosphatemia, and metaphyseal chondrodysplasia.¹⁴ It is the result of activating mutations of the gene for the PTH/PTHrP receptor, a particular form of pseudohyperparathyroidism.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia is a rare hereditary disease due to inactivating mutations in the gene for CaR_G^{15} with autosomal dominant transmission. It is characterized by moderate chronic hypercalcemia associated with hypophosphatemia, hyperchloremia, and hypermagnesemia. Plasma PTH concentration is normal or moderately elevated, and the fractional excretion of calcium is lower than that observed in hyperparathyroidism. The fractional excretion of calcium is best assessed by calculating the calcium to creatinine clearance ratio:

$$\text{calcium to creatinine clearance ratio} = \frac{(24\text{-hour urine calcium}) \times (\text{serum creatinine})}{(24\text{-hour urine creatinine}) \times (\text{serum calcium})}$$

In familial hypocalciuric hypercalcemia, the urine calcium to creatinine clearance ratio is usually less than 0.01. In patients with this syndrome, hypercalcemia never leads to severe clinical

signs (except during the neonatal period, in which malignant hypercalcemia can be observed in the context of severe hyperparathyroidism).

Other Endocrine Causes

Other endocrine disorders can be associated with moderate hypercalcemia, such as hyperthyroidism, acromegaly, and pheochromocytoma. In addition, acute adrenal insufficiency should also be considered in the differential diagnosis, although here hypercalcemia is usually false and results from hemoconcentration. Hypercalcemia can also occur in severe forms of the secondary hyperparathyroidism of CKD. However, this is relatively uncommon to date because low circulating calcitriol concentrations in CKD limit gastrointestinal calcium absorption¹⁶ and because parathyroid overfunction is often treated at earlier stages.

Other Causes

Several other disorders sometimes induce hypercalcemia. Among the granulomatoses, sarcoidosis results in increased plasma Ca^{2+} , particularly in patients exposed to sunlight. The cause is uncontrolled production of calcitriol by macrophages (due to the presence of the 1α -hydroxylase in the macrophages within the granulomas). Tuberculosis, leprosy, berylliosis, and many other granulomatous diseases are sometimes (but much more rarely than sarcoidosis) the origin of hypercalcemia, probably through the same mechanism.

Hypercalcemia may also result from prolonged bed rest (especially in patients with preexisting high bone turnover rates, such as children, adolescents, and patients with Paget's disease). Recovery from acute renal failure secondary to rhabdomyolysis-induced renal failure has been associated with hypercalcemia in 25% of cases and is thought to occur as a consequence of mobilization of soft tissue calcium deposits and through increases in PTH and calcitriol. Other causes include intoxication by vitamin D or one of its derivatives, vitamin A overload, and treatment by thiazide diuretics. Large doses of calcium (5 to 10 g/day), especially when ingested with alkali (antacids), can also lead to hypercalcemia and nephrocalcinosis (milk-alkali syndrome).

Clinical Manifestations

The severity of clinical symptoms and signs caused by hypercalcemia depends not only on the degree but also on the velocity of its development. Severe hypercalcemia can be accompanied by few manifestations in some patients because of its slow, progressive development, whereas much less severe hypercalcemia can lead to major disorders if it develops rapidly.

In general, the first symptoms are increasing fatigue, muscle weakness, inability to concentrate, nervousness, increased sleepiness, and depression. Subsequently, gastrointestinal signs may occur, such as constipation, nausea and vomiting, and, rarely, peptic ulcer disease or pancreatitis. Renal-related signs include polyuria (secondary to nephrogenic diabetes insipidus), urinary tract stones and their complications, and occasionally tubulointerstitial disease with medullary and to a lesser extent cortical deposition of calcium (nephrocalcinosis). Neuropsychiatric manifestations include headache, loss of memory, somnolence, stupor, and, rarely, coma. Ocular symptoms include conjunctivitis from crystal deposition and, rarely, band keratopathy. Osteoarticular pain in primary hyperparathyroidism has become rare in Western countries because of earlier diagnosis of hypercalcemia. High blood pressure can be induced by hypercalcemia,

but it is more frequently a chance association. Soft tissue calcifications can occur with long-standing hypercalcemia. Electrocardiography may show shortening of the QT interval and coving of the ST wave. Hypercalcemia may also increase cardiac contractility and can amplify digitalis toxicity.

Diagnosis

When the history and clinical examination are not helpful, primary hyperparathyroidism should be investigated first. Although this is only the second most frequent cause, its laboratory diagnosis is at present easier than that of tumoral involvement. In addition to total plasma calcium and ionized Ca^{2+} , plasma levels of albumin (or total protein), phosphate, creatinine, total alkaline phosphatase, and PTH and urinary concentrations of calcium and creatinine should be determined. Note that prolonged hypercalcemia is often associated with (reversible) increased serum creatinine. When plasma PTH is high or inappropriately normal with respect to the degree of hypercalcemia, the diagnosis is confirmed. Cervical ultrasonography and sestamibi isotope scanning may be performed to locate a parathyroid adenoma; but in general, experienced surgeons consider these examinations unnecessary before a first neck exploration. However, imaging is indispensable in recurrent hyperparathyroidism. If the plasma PTH level is low-normal or low, the possibility of a neoplastic disorder should be seriously considered. A low serum anion gap may be a clue to multiple myeloma (because occasionally the monoclonal IgG is positively charged). In addition to the usual examinations, such as serum protein electrophoresis, measurement of the plasma PTHrP level can now be done in specialized laboratories. Exogenous vitamin D overload is associated with increased serum 25-hydroxyvitamin D levels, and granulomatous diseases such as sarcoidosis are associated with elevated calcitriol levels and with increased serum angiotensin-converting enzyme activity.

Treatment

Treatment is aimed at the underlying cause. However, severe and symptomatic hypercalcemia requires rapid correction, whatever the cause. Initially, the patient must be rapidly rehydrated with isotonic saline for correction of the often marked volume depletion to reduce proximal tubule calcium reabsorption and to enhance calcium excretion. Only when euolemia is established should loop diuretics be used (e.g., intravenous furosemide in every other hour) to facilitate urinary excretion of calcium; however, intravenous saline should be continued to prevent hypovolemia. Oral intake and intravenous administration of fluids and electrolytes should be carefully monitored and urinary and gastric excretions measured if excessive, especially those of potassium, magnesium, and phosphate. Acid-base balance should also be carefully monitored. Severe cardiac failure and CKD are contraindications to massive extracellular fluid volume expansion in conjunction with diuretics.

Bisphosphonates are the treatment of first choice, especially in hypercalcemia associated with cancer.¹⁷ They inhibit bone resorption as well as calcitriol synthesis. They can be administered orally in less severe disease or intravenously in severe hypercalcemia. Frequently used bisphosphonates are clodronate (1600 to 3200 mg/day orally), pamidronate (15 to 90 mg intravenously during 1 to 3 days, once per month), and alendronate (10 mg/day orally). With intravenous administration, doses should be infused in 500 ml of isotonic saline or dextrose during

at least 2 hours and up to 24 hours. Treatment of hypercalcemia with bisphosphonates may be complicated by concomitant renal impairment because of package warnings contraindicating bisphosphonate use in patients with kidney disease. However, there are virtually no clinical data to support these warnings, and bisphosphonates have been safely used in patients with CKD for the correction of hypercalcemia. A reasonable strategy is first to attempt correction of acute kidney injury (AKI) before a bisphosphonate is administered and to avoid repetitive dosing; a single 60 mg dose of pamidronate can maintain normal calcium concentrations for weeks. Calcitonin acts within hours, in particular after intravenous administration. Human, porcine, or salmon calcitonin can be given. However, calcitonin often has no effect or only a short-term effect because of the rapid development of tachyphylaxis.

Mithramycin is a cytostatic drug with a remarkable power to inhibit bone resorption. Administration of a single intravenous dose is generally followed by a rapid decline in plasma calcium within a few hours, and this effect lasts several days. However, its use is reserved for malignant hypercalcemia, and its cytotoxic effect and side effects (thrombocytopenia and liver function abnormalities) preclude prolonged administration. The maximal daily dose is 25 $\mu\text{g/kg}$.

Corticosteroids (0.5 to 1.0 mg/kg prednisolone daily) are mainly indicated in hypervitaminosis D of endogenous origin, such as sarcoidosis and tuberculosis, and of exogenous origin, such as vitamin D intoxication. Ketoconazole, an antifungal agent that can inhibit renal and extrarenal calcitriol synthesis, has also been proposed in hypervitaminosis D. Corticosteroids can also be tried in the treatment of hypercalcemia associated with some hematopoietic tumors, such as myeloma and lymphoma, and even for some solid tumors, such as breast cancer.

In rare cases of malignant hypercalcemia, treatment with prostaglandin antagonists, for example, indomethacin or aspirin, can be successful. Hyperkalemia and impaired renal function may occur with indomethacin. Hypercalcemia caused by thyrotoxicosis can rapidly resolve with intravenous administration of propranolol or less rapidly with oral administration.

In moderate and nonsymptomatic hypercalcemia of primary hyperparathyroidism, treatment with estrogens has been tried, at least in women. In patients with primary hyperparathyroidism, cinacalcet, the first of a new therapeutic class of CaR_G agonists (calcimimetics), can achieve normalization of serum Ca^{2+} concentration in most instances together with a reduction of serum PTH.¹⁸ In dialysis patients with secondary and many cases of so-called tertiary uremic hyperparathyroidism, long-term administration of cinacalcet is superior to standard therapy in controlling serum PTH, calcium, and phosphorus concentrations.¹⁹ Cinacalcet is also effective in patients with parathyroid carcinoma.

HYPOCALCEMIA

Like hypercalcemia, hypocalcemia can be secondary either to reduced plasma albumin (false hypocalcemia) or to a change in ionized Ca^{2+} (true hypocalcemia). False hypocalcemia can be excluded by direct measurement of plasma Ca^{2+} , by determination of plasma total protein or albumin levels, by the clinical context, or by other laboratory results. Acute hypocalcemia is often observed during acute hyperventilation and the respiratory alkalosis that follows, regardless of the cause of hyperventilation. Hyperventilation can occur secondary to cardiopulmonary or cerebral diseases.

After exclusion of false hypocalcemia linked to hypoalbuminemia, hypocalcemia can be divided into that associated with elevated and that associated with low plasma phosphate concentration.

Hypocalcemia Associated with Hyperphosphatemia

This form of hypocalcemia is caused by hypoparathyroid states that are idiopathic or acquired (after surgery or radiotherapy or secondary to amyloidosis). Sporadic cases of hypoparathyroidism can occasionally be seen in patients with pernicious anemia or adrenal insufficiency. Pseudohypoparathyroidism (Albright's hereditary osteodystrophy) is characterized by a particular phenotype including short neck, round face, and short metacarpals, with end-organ resistance to PTH. CKD, AKI in its oligoanuric phase (e.g., secondary to rhabdomyolysis), and massive phosphate administration can also lead to hypocalcemia with hyperphosphatemia. At least one form of inherited, familial hypocalcemia is linked to particular activating mutations of the CaR_G .²⁰

Hypocalcemia Associated with Hypophosphatemia

Hypocalcemia with hypophosphatemia may occur from vitamin D-deficient states. This may result from insufficient sunlight exposure, dietary deficiency of vitamin D, decreased absorption after gastrointestinal surgery, intestinal malabsorption syndromes (steatorrhea), or hepatobiliary disease (primary biliary cirrhosis). Magnesium deficiency may also result in hypocalcemia, often in conjunction with hypokalemia, which may be due to inappropriate kaliuresis or diarrhea. The low serum Ca^{2+} concentration appears to result from decreased PTH release and end-organ resistance. AKI in the polyuric phase may also be associated with hypocalcemia and hypophosphatemia. The main causes of hypocalcemia are shown in Figure 10.10.

Clinical Manifestations

As with hypercalcemia, the symptoms of hypocalcemia depend on the rate of its development and its severity. The most common manifestations, in addition to fatigue and muscle weakness, are increased irritability, loss of memory, a state of confusion, hallucination, paranoia, and depression. The best known clinical signs are Chovstek's sign (tapping of facial nerve branches leads to twitching of facial muscle) and Trousseau's sign (carpal spasm in response to forearm ischemia caused by sphygmomanometer cuff). In acute hypocalcemia, there may be paresthesias of the lips and the extremities, muscle cramps, and sometimes frank tetany, laryngeal stridor, or convulsions. Chronic hypocalcemia can be associated with cataracts, brittle nails with transverse grooves, dry skin, and decreased or even absent axillary and pubic hair, especially in idiopathic hypoparathyroidism, which is often of autoimmune origin.

Laboratory and Radiographic Signs

Plasma phosphate is elevated in hypoparathyroidism, pseudohypoparathyroidism, and advanced CKD, whereas it is decreased in steatorrhea, vitamin D deficiency, acute pancreatitis, and the polyuric phase during recovery from AKI. Plasma PTH is reduced in hypoparathyroidism and also during chronic magnesium deficiency, whereas it is normal or increased in pseudohypoparathyroidism and in CKD. Urinary calcium excretion is

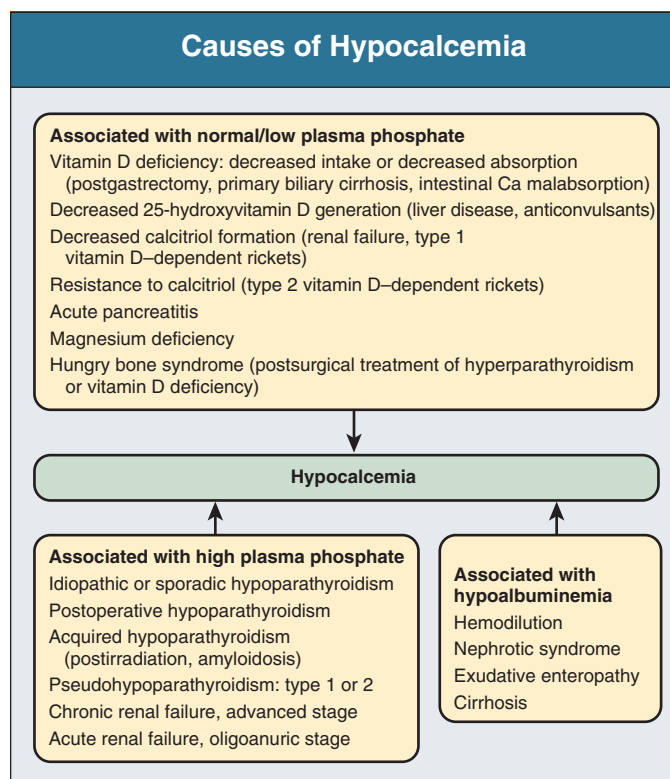

Figure 10.10 Causes of hypocalcemia.

increased only in the treatment of hypoparathyroidism with calcium and vitamin D derivatives, in which it may lead to nephrocalcinosis; it is low in all other cases of hypocalcemia. Fractional urinary calcium excretion is, however, high in hypoparathyroidism, in the polyuric phase during recovery from AKI, and in severe CKD; it is low in all other cases of hypocalcemia. Urinary phosphate excretion is low in hypoparathyroidism, pseudohypoparathyroidism, and magnesium deficiency; it is high in vitamin D deficiency, steatorrhea, and CKD and during phosphate administration. Determination of serum 25-hydroxyvitamin D and calcitriol levels may also be useful.

Intracranial calcifications, notably of the basal ganglia, are observed radiographically in 20% of patients with idiopathic hypoparathyroidism but much less frequently in patients with postsurgical hypoparathyroidism or pseudohypoparathyroidism.

On electrocardiography, the corrected QT interval is frequently prolonged, and there are sometimes arrhythmias. Electroencephalography shows nonspecific signs, such as an increase in slow, high-voltage waves.

Treatment

The basic treatment is that of the underlying cause. Severe and symptomatic (tetany) hypocalcemia requires rapid treatment. Acute respiratory alkalosis, if present, should be corrected, if possible. When the cause is functional, the simple retention of carbon dioxide (e.g., by breathing into a paper bag) may suffice. In other cases and to obtain a prolonged effect, intravenous infusion of calcium salts is most often required. In the setting of seizures or tetany, calcium gluconate should be administered as an intravenous bolus (for instance, calcium gluconate, 10 ml 10% w/v [2.2 mmol of calcium], diluted in 50 ml of 5% dextrose or isotonic saline), followed by 12 to 24 g during 24 hours in 5%

dextrose or isotonic saline. Calcium gluconate is preferred to calcium chloride, which can lead to extensive skin necrosis in accidental extravasation.

Treatment of chronic hypocalcemia includes oral administration of calcium salts, thiazide diuretics, or vitamin D. Several oral preparations of calcium are available, each with its advantages and disadvantages. The amount of elemental calcium of the various salts differs greatly. For example, the calcium content is 40% in carbonate, 36% in chloride, 12% in lactate, and only 8% in gluconate salts. The daily amount prescribed can be 2 to 4 g elemental calcium. Concurrent magnesium deficiency (serum $Mg^{2+} < 0.75$ mmol/l) should be treated either with oral magnesium oxide (250 to 500 mg every 6 days) or with magnesium sulfate: intramuscular (4 to 8 mmol/day) or intravenous (2 g i.v. over 2–4 hours, then as needed to correct deficiency).

Treatment of hypocalcemia secondary to hypoparathyroidism is difficult as urinary calcium excretion increases markedly with calcium supplementation and can lead to nephrocalcinosis and loss of renal function. To reduce urinary calcium concentration, thiazide diuretics can be used in association with restricted salt intake and high fluid intake.

Lastly, treatment with active forms of vitamin D, calcitriol or its analogue 1α -hydroxycholecalciferol (0.25 to 1.0 μ g/day), is the treatment of choice at present for idiopathic or acquired hypoparathyroidism because these compounds are better tolerated than massive doses of calcium salts. Administration of vitamin D derivatives generally leads to hypercalciuria and, rarely, to nephrocalcinosis. It requires regular monitoring of the serum calcium concentration to avoid hypercalcemia.

PHOSPHATE HOMEOSTASIS

Distribution of Phosphate in the Organism

Phosphorus plays a crucial role in cell structure and metabolism. Phosphorus is found in the organism as both mineral phosphate and organic phosphate (phosphoric esters). Within cells, phosphate regulates enzymatic activity and serves as an essential component of nucleic acids and phospholipid membranes. Outside cells, phosphate resides in bone and teeth as hydroxyapatite; less than 1% circulates in serum. Phosphate circulates as HPO_4^{2-} and $H_2PO_4^-$, in a 4:1 ratio at normal pH of 7.4. Normal serum phosphate levels of 2.8 to 4.5 mg/dl (0.9 to 1.5 mmol/l) fluctuate in a circadian rhythm, with levels approximately 0.6 mg/dl higher in the afternoon compared with an 11 AM nadir. **Figure 10.11** shows the distribution of phosphate in the extracellular and intracellular fluid compartments.

Figure 10.12 shows the balance of ingestion, body distribution, and excretion of phosphate in a healthy human. A young adult requires approximately 0.5 mmol/kg of phosphate daily. These needs are much higher in the child during growth. Phosphates are widely found in milk products, meat, eggs, and cereals and are used extensively as food additives.

Phosphate entrance into transport epithelia involves a secondary active Na^+ -phosphate (Na^+ -Pi) cotransport. Three different Na^+ -Pi cotransporters have been identified and characterized.²¹ The type 1 Na^+ -Pi family is present in the renal tubule and may also have anion channel function. Type 2 Na^+ -Pi cotransporters are the key players in phosphate homeostasis and include three members: NPT2a, NPT2b, and NPT2c. Two of them serve specific epithelial transport functions in the brush border of the proximal tubule (NPT2a, NPT2c) and of the small intestine (NPT2b), determining Na^+ -dependent phosphate

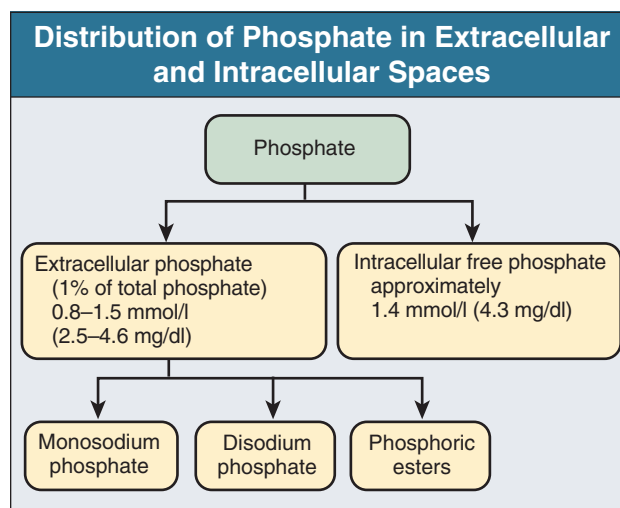

Figure 10.11 Distribution of phosphate in extracellular and intracellular spaces.

Figure 10.12 Phosphate homeostasis in healthy young adults. At net zero balance, identical net intestinal uptake (absorption minus secretion) and urinary loss occur. After its passage into the extracellular fluid, phosphate enters the intracellular space, is deposited in bone or soft tissue, or is eliminated by the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also the same under steady-state conditions. Values linked to compartments represent absolute amounts of phosphate whereas values linked to the intestine and the kidney represent daily phosphate entries and exits, and values between organs and compartments represent daily fluxes.

reabsorption. Type 3 Na^+ -Pi cotransporters, Pit1 and Pit2, are ubiquitous. Phosphate entry into vascular smooth muscle cells through Pit1 is believed to be a necessary first step for initiation of pathologic smooth muscle calcification. The exit of phosphate at the basolateral side of the intestinal and renal tubular epithelium probably occurs by anionic exchange.

The transcellular transport of phosphate is controlled by metabolic, hormonal, and autocrine and paracrine factors, including calcitriol, growth hormone, insulin-like growth factor

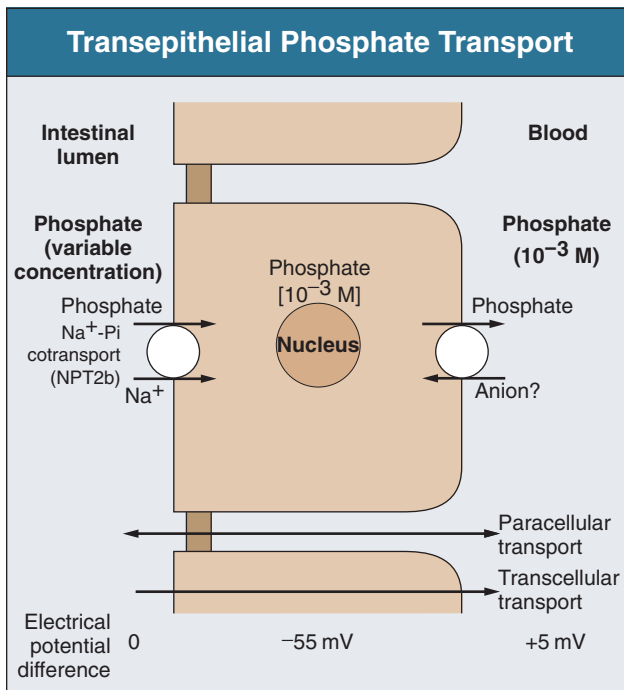

Figure 10.13 Transepithelial phosphate transport in the small intestine. Phosphate enters the enterocyte (influx) through the brush border membrane by the Na^+ -Pi cotransport system, with a stoichiometry of 2:1, operating against an electrochemical gradient. Phosphate exit at the basolateral side possibly occurs by passive diffusion or (more probably) by anion exchange.

1, insulin, and thyroid hormone. In the kidney, PTH and fibroblast growth factor (FGF) 23 are major phosphaturic hormones that promote urinary phosphate excretion. Several other phosphatonins have also been identified subsequently, including secreted frizzled-related protein 4 (sFRP-4), matrix extracellular phosphoglycoprotein, and FGF-7.²² The *klotho* protein participates directly in phosphate homeostasis by conferring specificity of the interaction of FGF-23 with its receptor FGF-R1. Deletion of *klotho* in the mouse induces a hyperphosphatemic phenotype. Of note, *klotho* also activates the calcium channel TRPV5.²³

Intestinal, Renal, and Skeletal Handling of Phosphate

Phosphate transport across the intestinal wall occurs through both the transepithelial and the paracellular routes (Fig. 10.13). Absorption is a linear, nonsaturable function of phosphate intake (Fig. 10.14) and amounts to 60% to 75% of total phosphate intake (15 to 50 mmol/day). Calcitriol, which stimulates the NPT2b cotransporter, is the major hormonal determinant of intestinal phosphate absorption. Cations, such as calcium, magnesium, and aluminum, bind to phosphate in the gastrointestinal tract, limiting its absorption. In both animals and humans, ingestion of a high-phosphate meal results in the rapid excretion of phosphate in the urine, without detectable changes in serum phosphate levels.

The kidneys play a major role in controlling extracellular phosphate homeostasis.^{24,25} Phosphate is freely filtered in the glomerulus and reabsorbed primarily in the proximal tubule of the kidney. Normally, the daily amount of phosphate excreted in urine equals that absorbed in the intestine, usually comprising 5% to 20% of the ultrafiltered phosphate load.

Figure 10.14 Relationship between ingested phosphate and that absorbed in the digestive tract (net absorption) in healthy young adults. (From reference 9.)

The amount of phosphate reabsorbed can be expressed in relation to the amount filtered as the urinary fractional excretion of phosphate (FE_{PO_4}):

$$\text{FE}_{\text{PO}_4} = (U_{\text{PO}_4} \times S_{\text{creat}}) / (S_{\text{PO}_4} \times U_{\text{creat}})$$

where U_{PO_4} , S_{PO_4} , U_{creat} , and S_{creat} are urinary and serum phosphate and creatinine concentrations, respectively. Alternatively, the amount of phosphate reabsorbed can be expressed as the fraction (or percent) of filtered phosphate that is reabsorbed by the renal tubule (TRP, %). The maximal tubular reabsorption of phosphate (TmP) factored for GFR (TmP/GFR , Bijvoet index) represents the concentration above which most phosphate is excreted and below which most is reabsorbed. This can be calculated from the plasma phosphate concentration and tubular reabsorption of phosphate (Fig. 10.15).

After passage through the glomerulus, part of the filtered phosphate load is recovered by the tubule, depending on the body's needs. The major fraction of phosphate is reabsorbed in the proximal convoluted tubule through NPT2a, which is modulated by endocrine and metabolic factors.²⁵ Specifically, PTH, FGF-23, and hyperphosphatemia downregulate NPT2a, increasing urinary phosphate excretion, whereas hypophosphatemia upregulates NPT2a, decreasing urinary phosphate excretion.

Recent attention has focused on FGF-23 as a master regulator of phosphate metabolism. FGF-23 lowers serum phosphate concentrations by decreasing renal phosphate reabsorption and by inhibiting calcitriol production, thereby reducing phosphate absorption in the gut. Genetic disruption of FGF-23 in animals results in hyperphosphatemia, calcitriol toxicity, vascular calcification, and premature death. An identical phenotype is created by genetic disruption of *klotho*, which is needed for FGF-23 to bind its receptor in the renal proximal tubule and to enhance phosphate excretion. It has been proposed very recently that *klotho* could also have a direct phosphaturic action in the proximal tubule, independent of FGF23, via an enzymatic modification of apical membrane glycans.

Bone permanently exchanges phosphate with the surrounding milieu. Entry and exit of phosphate amount to approximately 100 mmol/day (slowly exchangeable phosphate), for a total skeleton content of approximately 20,000 mmol. The net balance is positive during growth, zero in the young adult, and negative in the elderly.

Figure 10.15 Nomogram for estimation of the renal threshold phosphate concentration (TmP/GFR) without any calculation. A straight line through the appropriate values of phosphate concentration and tubular reabsorption of phosphate (TRP, amount of phosphate reabsorbed) or C_P/C_{cr} (where C is clearance for phosphate [P] or creatinine [cr]) passes through the corresponding value of TmP/GFR. $TRP = 1 - \text{FePO}_4 = 1 - (\text{UPO}_4 \times \text{Screat}) / (\text{SPO}_4 \times \text{Ucreat})$ (From reference 26.)

HYPERPHOSPHATEMIA

Causes of Hyperphosphatemia

The most common cause of increased serum phosphate levels is reduced urinary excretion in AKI and CKD.²⁷ Although hyperphosphatemia is seen particularly in conditions in which urinary phosphate excretion is perturbed, it can also be caused by increased exogenous or endogenous phosphate supply (Fig. 10.16).

Acute Kidney Injury

An acute reduction in GFR leads directly to a rise in the serum phosphate level, often in parallel with the serum creatinine level. Phosphate levels can be extremely high when there is concomitant release of phosphate from tissues, as in rhabdomyolysis.

Chronic Kidney Disease

Despite a gradual loss of filtering nephrons in CKD, serum phosphate levels are generally preserved until the GFR falls below about 35 mL/min per 1.73 m². Preservation of serum phosphate levels in CKD highlights the complex regulatory mechanisms involved in phosphate homeostasis. Phosphate retention with impaired kidney function parallels a rise in circulating levels of the phosphaturic hormones PTH and FGF-23, which defend serum phosphate levels by increasing urinary phosphate excretion. Both hormones downregulate NPT2a on the apical surface of the proximal tubule, increasing the fractional excretion of phosphate, which can exceed 60% in advanced CKD. However, there is a price paid for defending the serum phosphate level; FGF-23 potently suppresses 25-hydroxyvitamin D 1 α -hydroxylase activity, possibly to limit further gastrointestinal absorption of phosphate, resulting in diminished calcium absorption and further stimulation of PTH. Eventually, reduced functional renal mass can no longer support further phosphate excretion, and serum phosphate levels rise. By this time, secondary hyperparathyroidism is usually evident, along with elevated levels of FGF-23 and lower levels of calcitriol and calcium.

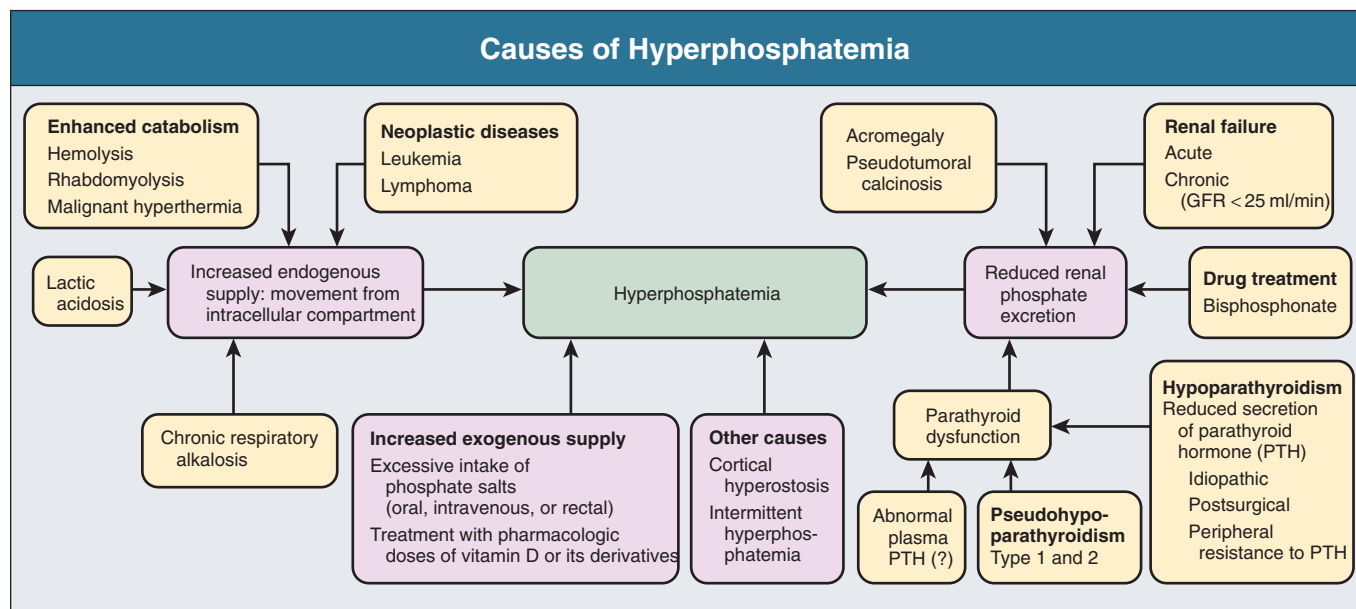

Figure 10.16 Causes of hyperphosphatemia.

Lytic States

Exaggerated phosphate loss by tissues can be observed in states of extreme cell lysis, particularly rhabdomyolysis (crush injury), or malignant neoplasms and their treatment (especially lymphomas and leukemias). The hyperphosphatemia of rhabdomyolysis is typically accompanied by hypocalcemia, myoglobinuria, and AKI. Severe hypercatabolic states during severe infection or in diabetic ketoacidosis can also cause hyperphosphatemia by increased cellular release of phosphate (which is usually accompanied with an acute reduction in GFR).

Treatment-Induced Hyperphosphatemia

A massive supply of phosphate, as may occur by phosphate-based laxative or enema use, can lead to hyperphosphatemia. Oral sodium phosphate solutions used to prepare for colonoscopy contain massive quantities of phosphate and can cause precipitation of calcium phosphate crystals within the renal tubules and AKI. Recovery from this condition is slow and often incomplete, with some cases resulting in permanent dialysis. For these reasons, bowel preparations other than those based on sodium phosphate salts should be used in patients with CKD. Bisphosphonates, in particular etidronate in Paget's disease, can sometimes increase serum phosphate levels, possibly through increased liberation of tissue phosphate or an increase in renal tubular reabsorption.

Hypoparathyroidism

PTH is a major phosphaturic hormone. In states of reduced PTH secretion (idiopathic or postsurgical hypoparathyroidism) or resistance to its peripheral action (pseudohypoparathyroidism), tubular excretion of phosphate is diminished. The resulting increase in plasma phosphate leads to an increase in the ultrafiltered load. This results in the regulation of plasma phosphate at a new steady-state level.

Chronic Hypocalcemia

Hyperphosphatemia is sometimes observed in association with chronic hypocalcemia with normal or high plasma PTH levels. In the absence of characteristic abnormalities of pseudohypoparathyroidism, the existence of an abnormal form of plasma PTH has been suggested, perhaps due to abnormal conversion of the prohormone to its secreted form.

Acromegaly

In this condition, hyperphosphatemia results from an increase in tubular reabsorption of phosphate due to stimulation by growth hormones or insulin-like growth factor 1.

Familial Tumoral Calcinosis

This rare, autosomal recessive disorder seen primarily in people of Middle Eastern or African ancestry is caused by inactivating or missense mutations in the *GALNT3*, *FGF23* or *klotho* gene. Possibly the glycosyl transferase encoded by *GALNT3* is necessary for FGF-23 activity, thus resulting in a shared phenotype.²¹ The lack of functional FGF-23 results in an exaggerated tubular phosphate reabsorption and uninhibited vitamin D activation, leading to hyperphosphatemia, an elevated serum calcium \times phosphate product, high circulating levels of calcitriol, and metastatic soft tissue calcifications. Circulating PTH is not decreased.

Respiratory Alkalosis by Prolonged Hyperventilation

Respiratory alkalosis resulting from prolonged hyperventilation is characterized by resistance to the renal action of PTH,

Figure 10.17 Tumor-like extraskelatal calcification in the shoulder.

hyperphosphatemia, and hypocalcemia. There may also be functional pseudohypoparathyroidism because renal phosphate clearance is diminished, whereas plasma PTH is normal, despite hypocalcemia. There is no decrease in urinary calcium excretion.

Clinical Manifestations

Acute and severe hyperphosphatemia can induce hypocalcemia, which stimulates PTH but inhibits renal synthesis of calcitriol, which tends to further aggravate hypocalcemia. Chronic hyperphosphatemia is suspected to play a causal role in the pathogenesis of vascular calcification, particularly in CKD (see Chapter 78). In extreme cases, hyperphosphatemia can induce tumor-like soft tissue calcium phosphate deposits (Teutschländer's disease; Fig. 10.17) or extensive vascular calcification within the arteries of the skin (calciophylaxis or calcific uremic arteriolopathy; see Chapter 84).

Treatment

Treatment of acute hyperphosphatemia is usually targeted at improving phosphate excretion either by intravenous fluids or by renal replacement therapy in cases of severe AKI. Intravenous dextrose and insulin can also shift phosphate into cells, similar to its use for treatment of hyperkalemia. Treatment of chronic hyperphosphatemia typically requires the use of an oral phosphate binder, usually calcium acetate, calcium carbonate, sevelamer, or lanthanum carbonate, which complex with phosphate in the gastrointestinal tract and limit absorption (see Chapter 78).

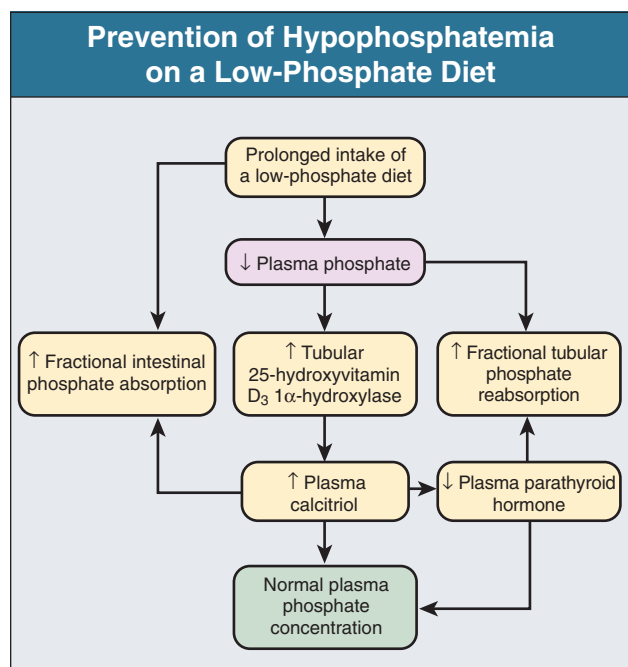

Figure 10.18 Compensatory mechanisms to prevent hypophosphatemia during a prolonged intake of a phosphate-poor diet.

HYPOPHOSPHATEMIA

Decreased plasma phosphate levels may reflect phosphate deficiency. This can, theoretically, be observed during a prolonged decrease in phosphate intake. However, as shown in [Figure 10.18](#), several defense mechanisms counter a decrease in plasma phosphate resulting from low intake. Moderately reduced plasma phosphate levels may also be seen with maldistribution between the intracellular and extracellular compartments during acute respiratory alkalosis.

Causes of Hypophosphatemia

Moderate hypophosphatemia can be caused by genetic diseases or by acquired conditions ([Fig. 10.19](#)).³² The main acquired condition is malnutrition due to low food intake or anorexia during critical illness or alcoholism. Another cause is a shift of phosphate into cells, which can occur through various mechanisms, but especially with the administration of insulin. Although there are a large number of genetic diseases and syndromes, overall, these are rare. Severe forms of hypophosphatemia are all acquired.

Inherited Forms of Hypophosphatemia

Inherited diseases associated with chronic hypophosphatemia are generally diagnosed in childhood. Persistently low plasma phosphate usually leads to rickets or osteomalacia. Inherited hypophosphatemia results from primary defects that are either isolated or associated with tubular disorders (Fanconi syndrome) or defects secondary to another genetically transmitted disease, mainly metabolic disorders or disturbances in the action of vitamin D.

Autosomal Dominant Hypophosphatemic Rickets

Children with this phosphate-wasting disorder present with skeletal defects, including bowing of the long bones and widening of costochondral joints. The disease is linked to mutations in *FGF-23*, in which an aberrant form of the molecule is resistant to

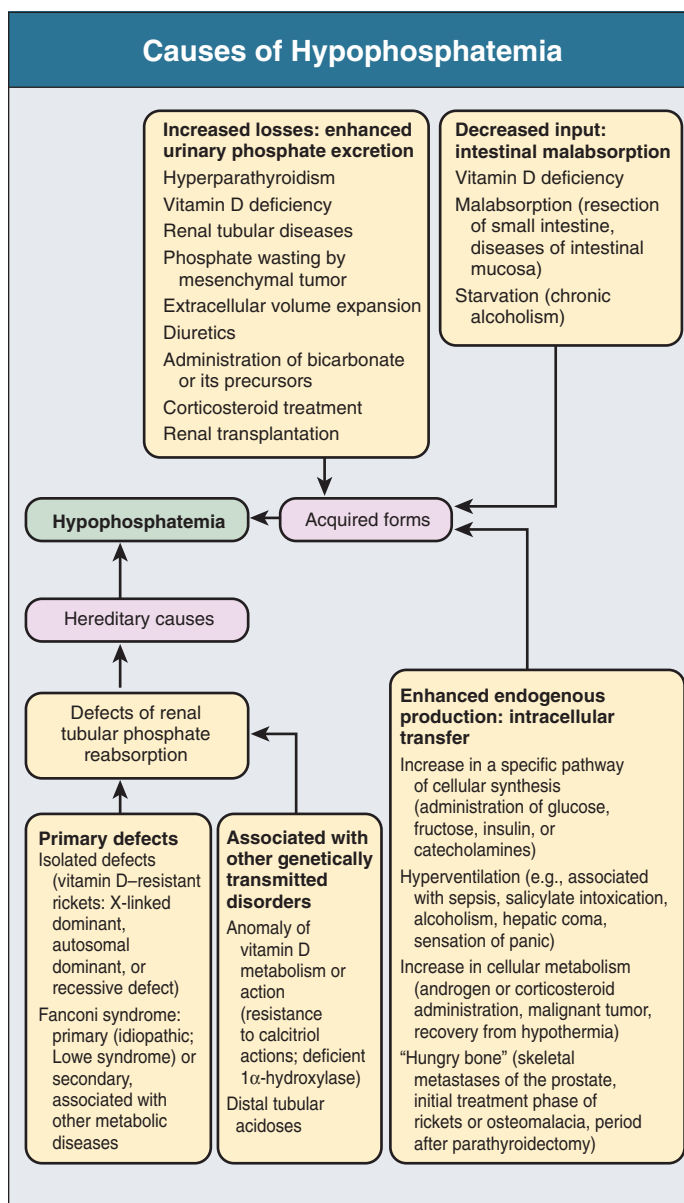

Figure 10.19 Causes of hypophosphatemia.

proteolytic cleavage.²⁸ Excess FGF-23 causes phosphate wasting by downregulation of NPT2a in the proximal renal tubule.

X-Linked Hypophosphatemic Rickets

This rare phosphate-wasting syndrome is characterized by skeletal deformities, short stature, and osteomalacia. The disease has been linked to various mutations in the *PHEX* gene (phosphate-regulating endopeptidase on the X chromosome). *PHEX* was believed to play a role in the proteolysis of FGF-23 but recent findings cast doubt on this hypothesis, so another mechanism needs to be identified.²⁹ *PHEX* mutations result in high circulating FGF-23 concentrations, renal phosphate wasting, and hypophosphatemia. Plasma calcium, calcitriol, and PTH levels are normal, and the alkaline phosphatase level is elevated.

Autosomal Recessive Hypophosphatemic Rickets

This disorder is caused by mutations in the gene encoding dentin matrix protein 1 (*DMP1*), which is believed to suppress FGF-23 secretion by bone.

Fanconi Syndrome and Proximal Renal Tubular Acidosis

Fanconi syndrome (see Chapter 48) is characterized by a complex transport defect of the proximal tubule that results in decreased reabsorption of glucose, amino acids, bicarbonate, and phosphate. Because 70% of the filtered phosphate load is typically reabsorbed in the proximal tubule, Fanconi syndrome can lead to phosphate wasting and hypophosphatemia. Causes of Fanconi syndrome can be primary (idiopathic, Lowe syndrome, Dent disease) or associated with other metabolic diseases (cystinosis, Wilson's disease, and others). In Dent disease and Lowe syndrome, a defective recycling of megalin to the apical cell surface of the proximal tubule has been found, implicating a role in abnormal tubular endocytic function.³⁰

Fanconi syndrome with phosphate wasting can also occur as an acquired disorder in adults. Common causes are multiple myeloma and specific medications (tenofovir, ifosfamide, and carbonic anhydrase inhibitors).

In addition to a tubular defect causing phosphate wasting, the activity of renal 25-hydroxyvitamin D 1 α -hydroxylase may be insufficient, resulting in decreased circulating calcitriol levels and bone disease such as rickets and osteomalacia. Functional disorders associated with the syndrome, such as polyuria and extracellular volume contraction, lead to hyperaldosteronism with hypokalemia and eventually to renal failure.

Hypophosphatemia Linked to Other Inherited Diseases

Several rare inherited diseases can be associated with hypophosphatemia, including vitamin D–dependent rickets type 1, caused by a defect of renal 25-hydroxyvitamin D 1 α -hydroxylase, and type 2, caused by peripheral resistance to the action of calcitriol. Clinical signs are similar to those of vitamin D–deficient rickets, but alopecia also occurs in 50% of cases. In type 1, calcitriol levels are low, whereas in type 2, there is normal circulating 25-hydroxyvitamin D and high calcitriol. Low doses of calcitriol are sufficient for treatment of type 1, whereas extremely high doses of calcitriol or alfacalcidol are required for type 2.

Distal Renal Tubular Acidosis (Type 1)

Distal renal tubular acidosis (type 1; see Chapter 12) is associated with hypercalciuria and sometimes nephrocalcinosis because chronic acidosis enhances the reabsorption of citrate in the proximal tubule, preventing it from forming soluble calcium-citrate complexes in the urine. Chronic acidosis also causes increased calcium and phosphate release from bone. Hypophosphatemia is inconsistent; it is possible that it results only when there is concomitant vitamin D deficiency.

Acquired Forms of Hypophosphatemia

The number of acquired diseases that can be associated with hypophosphatemia is even greater than the number of inherited diseases and includes hyperparathyroidism and vitamin D deficiency (see Fig. 10.19). True phosphate deficiency associated with total body depletion must be distinguished from enhanced influx of phosphate from the extracellular to the intracellular space or increased skeletal mineralization.

Alcoholism

Alcoholism is the most common cause of severe hypophosphatemia in Western countries. The causes are multiple, including prolonged insufficient food intake, excessive phosphate loss in urine secondary to hypomagnesemia, and phosphate transfer from the extracellular to the intracellular compartment second-

ary to hyperventilation or glucose infusion in subjects with post-alcoholic cirrhosis or in acute abstinence.

Hyperparathyroidism

PTH enhances urinary phosphate excretion by downregulation of the NPT2a cotransporter. Patients with primary hyperparathyroidism typically present with mild hypercalcemia and hypophosphatemia.

Post-Transplantation Hypophosphatemia

Renal phosphate wasting is exceedingly common in both cadaveric and living related renal transplant recipients. Most renal transplant patients develop hypophosphatemia at some point during their post-transplantation course, and in some instances, the condition may be prolonged. A number of explanations for this condition have been proposed, including residual hyperparathyroidism from chronic kidney failure; however, the best evidence implicates persistently high circulating levels of FGF-23 as the key factor responsible for post-transplantation urinary phosphate wasting.

Acute Respiratory Alkalosis

In intense and short-term hyperventilation, plasma phosphate can sometimes decrease considerably to values as low as 0.1 mmol/l (0.3 mg/dl). Such a decrease is never observed in acute metabolic alkalosis. Hypophosphatemia that follows acute and intense hyperventilation is probably the result of muscle sequestration of extracellular phosphate. However, prolonged chronic hyperventilation leads to hyperphosphatemia (see previous discussion).

Diabetic Ketoacidosis

During decompensated diabetes associated with acidosis provoked by accumulation of ketone bodies, glycosuria, and polyuria, plasma phosphate can be normal or high, even in the presence of hyperphosphaturia. Correction of this complication by insulin and refilling of the extracellular compartment leads to massive transfer of phosphate into the intracellular compartment, hypophosphatemia, and subsequently less urinary loss of phosphate. In general, plasma phosphate does not decrease to less than 0.3 mmol/l (0.9 mg/dl), except when there is preexisting phosphate deficiency.

Total Parenteral Nutrition

Hyperalimentation can also be associated with severe hypophosphatemia through the insulin-mediated shift of phosphate into cells, particularly if phosphate is omitted from the parenteral nutrition solution. Severe hypophosphatemia can also occur with acute feeding after starvation.

Oncogenic Hypophosphatemic Osteomalacia

Hypophosphatemia associated with tumor-induced osteomalacia results from renal phosphate wasting in patients with mesenchymal tumors (hemangiopericytomas, fibromas, angiosarcomas). The mechanism of hypophosphatemia is tumor secretion of phosphatonins (FGF-23, sFRP-4, matrix extracellular phosphoglycoprotein [MEPE], or FGF-7).²⁶ The condition resolves after tumor resection.

Drug-Induced Hypophosphatemia

Imatinib mesylate, a tyrosine kinase inhibitor, has been reported to cause hypophosphatemia and an elevation in PTH levels. The mechanism of action is not yet clear.

Clinical Manifestations

Clinical manifestations depend on the rate of onset of hypophosphatemia more than on its severity or the total body phosphate deficit. In practice, it is not clinically evident when serum phosphate concentration is more than 0.65 mmol/l (2.0 mg/dl). Manifestations include metabolic encephalopathy, red and white blood cell dysfunction, sometimes hemolysis, and thrombocytopenia. Reduced muscle strength and decreased myocardial contractility (with occasional rhabdomyolysis and cardiomyopathy, respectively) may occur.

Treatment

Phosphate deficiency is generally not an emergency. First, the mechanism involved should be defined to determine the most appropriate treatment.

When phosphate deficiency is diagnosed, oral treatment by milk products or phosphate salts should always be tried first whenever possible, except in the presence of nephrocalcinosis or nephrolithiasis with urinary phosphate wasting. In severe symptomatic deficiency, phosphate can also be infused intravenously, in divided doses during 24 hours. In patients undergoing parenteral nutrition, 10 to 25 mmol potassium phosphate should be given for each 1000 kcal, with care taken to avoid hyperphosphatemia because of the risk of inducing soft tissue calcifications. Dipyridamole (300 mg divided into four doses per day) has been shown to reduce the urinary excretion of phosphate in patients with a low renal phosphate threshold.

MAGNESIUM HOMEOSTASIS AND DISORDERS OF MAGNESIUM METABOLISM

Distribution of Magnesium in the Organism and Magnesium Homeostasis

Magnesium (Mg) is, after potassium, the second most abundant cation in the intracellular fluid in living organisms. Mg^{2+} is involved in the majority of metabolic processes. In addition, it plays a part in DNA and protein synthesis. It is involved in the regulation of mitochondrial function, inflammatory processes and immune defense, allergy, growth, and stress, and in the control of neuronal activity, cardiac excitability, neuromuscular transmission, vasomotor tone, and blood pressure. The distribution of Mg^{2+} within the intracellular and extracellular spaces is shown in Figure 10.20.

Figure 10.21 shows the balance of ingestion, body distribution, and excretion of Mg^{2+} in healthy humans. Mg^{2+} influx into and efflux out of cells are linked to carbohydrate-dependent active transport systems. The stimulation of β -adrenoceptors favors Mg^{2+} outflux, whereas insulin, calcitriol, and vitamin B₆ favor Mg^{2+} entry into cells.

Intestinal and Renal Handling of Magnesium

The intestinal absorption of dietary magnesium occurs by both a saturable and a passive transport process, the major part being absorbed in the small intestine. The entry step in enterocyte brush border membrane is controlled by the magnesium channel TRPM6, which has been cloned recently and whose functional characterization is in progress.³ Mg^{2+} absorption can vary by as much as 25% to 60%, with a mean absorption of approximately 30%. Intestinal transport does not change in response to chronic

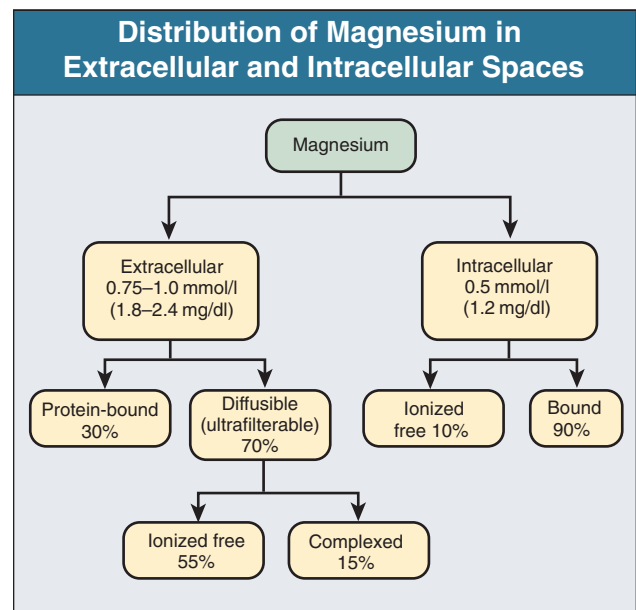

Figure 10.20 Distribution of magnesium in extracellular and intracellular spaces.

Figure 10.21 Magnesium homeostasis in the healthy young adult. Net zero balance results from net intestinal uptake (absorption minus secretion) equaling urinary loss. After its passage into the extracellular fluid, Mg^{2+} enters the intracellular space, is deposited in bone or soft tissue, or is eliminated by the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude; however, precise values of exchange are still debated. Values linked to compartments represent absolute amounts of magnesium whereas values linked to the intestine and the kidney represent daily magnesium entries and exits, and values between organs and compartments represent daily fluxes.

changes in dietary magnesium. However, TRPM6 is downregulated by an increase in intracellular Mg^{2+} .

Various factors modify intestinal Mg^{2+} absorption. High dietary phosphate intake is inhibitory, as is high phytate consumption. The effect of dietary calcium is complex, and vitamin D probably has an enhancing effect. Growth hormone

Figure 10.22 Sites of magnesium reabsorption in various segments of the renal tubule. The percentage absorbed in various segments from the glomerular ultrafiltrate is shown. (Redrawn from reference 33.)

slightly increases Mg^{2+} absorption, whereas aldosterone and calcitonin appear to reduce it. Vitamin B_6 has been reported to enhance it.

Mg^{2+} is eliminated by the kidney. Losses through intestinal secretion and sweat are negligible under normal conditions. With an ultrafilterable plasma magnesium concentration of 0.5 to 0.7 mmol/l (80% of total plasma magnesium), the filtered load of magnesium amounts to approximately 104 mmol (or 2500 mg) per day. The urinary output represents approximately 5% of the filtered load (4 to 5 mmol or 100 mg per day). The major portion of filtered magnesium is reabsorbed by the renal tubules (25% in the proximal tubule, 65% in the thick ascending loop of Henle, and 5% in the distal convoluted tubule) (Fig. 10.22).

Mg^{2+} transport in the thick ascending limb is primarily passive through the paracellular route. However, two conditions are necessary for normal Mg^{2+} reabsorption: first, the generation of an electrical, lumen-positive gradient induced by NaCl reabsorption that creates the driving force required for the reabsorption of divalent cations; and second, the expression of claudin 16 in the tight junction, which is responsible for the selectivity of the reabsorption of divalent cations. Different anomalies associated with NaCl reabsorption or with claudin 16 (formerly called paracellin) expression result in hypermagnesuria, for example, atypical cases of Bartter syndrome, which is defined by genetic

defects related to NaCl transport in the thick ascending limb (see also later discussion).³⁴

In the distal nephron, that is, the distal convoluted tubule and the connecting tubule, Mg^{2+} is reabsorbed through the transcellular route against an uphill electrochemical gradient. The molecular identity of the gatekeeper channel that controls Mg^{2+} entry into the tubular epithelium across the brush border membrane has been discovered recently as TRPM6.³ It is identical to that of the intestine.

Tubular Mg^{2+} transport is modulated by serum Mg^{2+} and Ca^{2+} and extracellular fluid volume. An increase of plasma Mg^{2+} or Ca^{2+} concentration results in a depression of magnesium transport. Extracellular volume expansion produces a decrease in proximal tubular Mg^{2+} reabsorption, in parallel with that of Na^+ and Ca^{2+} . Dietary phosphate restriction results in marked hypercalciuria and hypermagnesuria and can thereby lead to overt hypomagnesemia. PTH, vasopressin, calcitonin, and glucagon increase tubular Mg^{2+} reabsorption, whereas acetylcholine, bradykinin, and atrial natriuretic peptide stimulate urinary Mg^{2+} excretion.

Finally, a number of drugs have been shown to increase renal Mg^{2+} excretion, including the loop diuretics such as furosemide and ethacrynic acid, distal diuretics such as thiazides, and osmotic diuretics such as mannitol and urea. Thiazide

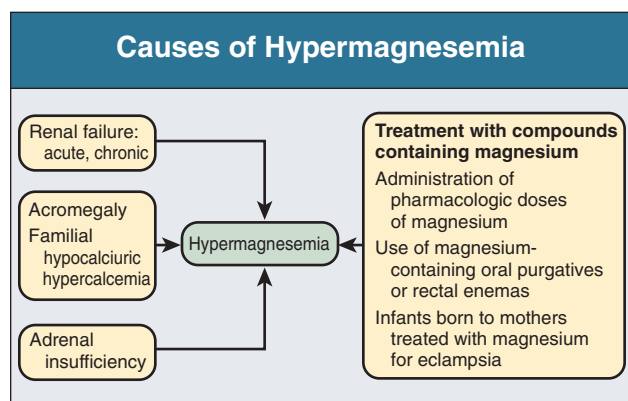

Figure 10.23 Causes of hypermagnesemia.

diuretics increase sodium delivery to the cortical collecting duct, dissipating the favorable electrochemical gradient for magnesium entry at this site. Furthermore, renal magnesium-wasting syndromes have been observed in patients treated with antibiotics such as gentamicin, antineoplastic agents such as cisplatin, and the calcineurin inhibitors cyclosporine and tacrolimus. The precise mechanisms of action of these agents are not well understood.

HYPERMAGNESEMIA

Elevated plasma Mg^{2+} is seen in patients with AKI and CKD, during the administration of pharmacologic doses of magnesium, in some infants born to mothers who received magnesium for eclampsia, and with the use of oral laxatives or rectal enemas containing magnesium (Fig. 10.23). Mild hypermagnesemia may also be present in patients with adrenal insufficiency, acromegaly, or familial hypocalciuric hypercalcemia.

Clinical Manifestations

Symptoms and signs are the result of the pharmacologic effects of increased Mg^{2+} concentrations on the nervous and cardiovascular systems. At Mg^{2+} concentrations up to 1.5 mmol/l (3.6 mg/dl), hypermagnesemia is asymptomatic. Deep tendon reflexes are usually lost when plasma Mg^{2+} concentration is greater than 3 mmol/l (7.2 mg/dl). Respiratory paralysis, hypotension, abnormal cardiac conduction, and loss of consciousness may occur as plasma levels of magnesium approach 5 mmol/l (12 mg/dl).

Treatment

Treatment consists of cessation of magnesium administration and the intravenous infusion of calcium salts. For the management of symptomatic hypermagnesemia, calcium gluconate may be given intravenously as 1 g in 10 ml during 5 to 10 minutes (each gram of calcium gluconate is equal to approximately 90 mg of elemental calcium).

HYPOMAGNESEMIA AND MAGNESIUM DEFICIENCY

Magnesium deficiency is defined as a decrease in total body magnesium content. Poor dietary intake of magnesium is usually not associated with marked magnesium deficiency because of the

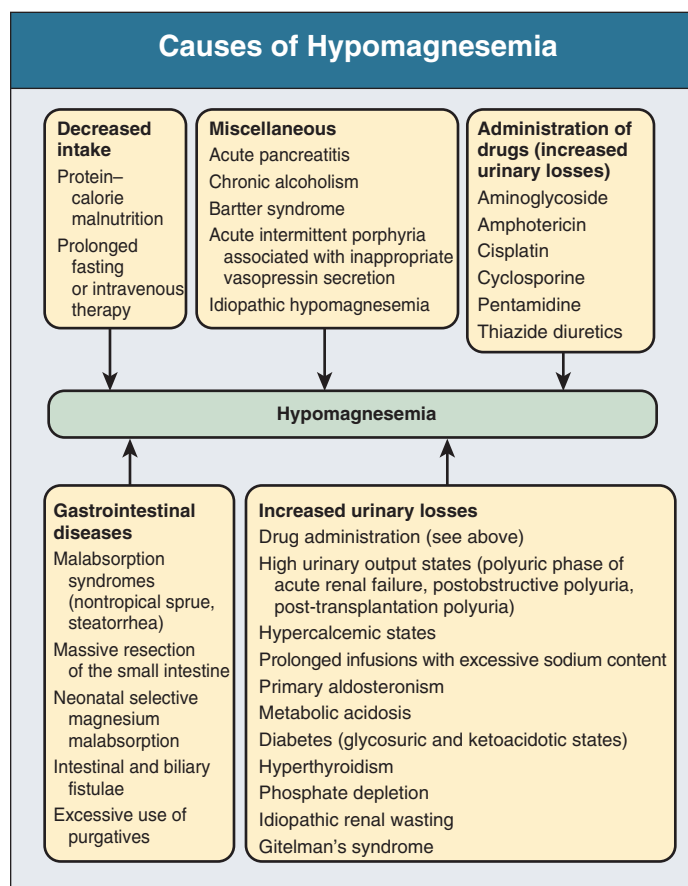

Figure 10.24 Causes of hypomagnesemia.

remarkable ability of the normal kidney to conserve Mg^{2+} . However, prolonged and severe dietary magnesium restriction of less than 0.5 mmol/day can produce symptomatic magnesium deficiency. Severe hypomagnesemia is usually associated with magnesium deficiency. Approximately 10% of patients admitted to a large city hospital in the United States were hypomagnesemic. The incidence may be as high as 65% in medical intensive care units.

Underlying causes are usually diseases of the gastrointestinal tract, in particular malabsorption syndromes including nontropical sprue, and massive resection of the small intestine. Hypomagnesemia can also be induced by prolonged tube feeding without magnesium supplements and by the excessive use of laxatives (Fig. 10.24).

Hypomagnesemia is encountered in about 25% to 35% of patients with acute pancreatitis, is frequently observed in patients with chronic alcoholism, and can also be present in patients with poorly controlled diabetes mellitus. Hypomagnesemia can also be observed in patients with hypercalcemic disorders and in primary aldosteronism.

Excessive urinary loss of magnesium leads to hypomagnesemia and magnesium deficiency, even in the face of normal dietary intake. It may result from the overzealous use of diuretics; therefore, it is important to monitor plasma Mg^{2+} levels in patients with congestive heart failure who are treated with diuretic agents. Other drugs that may cause hypomagnesemia include gentamicin, cisplatin, and the calcineurin inhibitors cyclosporine and tacrolimus.

Several familial diseases are associated with hypermagnesuria, with or without hypomagnesemia. They are due to inactivating

mutations of genes whose abnormal products are responsible for disturbed Mg^{2+} reabsorption in the thick ascending limb of Henle or in the distal nephron. Inactivating mutations of the genes of the Na-K-2Cl cotransporter, the rectifying K^+ channel (ROMK), or the basolateral Cl^- channel in Bartter syndrome are responsible for the abolition of the driving force for Mg^{2+} reabsorption. This can result in hypermagnesuria, which, however, is only rarely associated with hypomagnesemia. Inactivating mutations of the gene encoding CaR_G , whose protein product is a key regulator of NaCl reabsorption in the thick ascending limb through extracellular Ca^{2+} concentration, lead to hypermagnesuria and hypomagnesemia. A mutation of the gene encoding claudin 16 (previously paracellin 1) has been reported to induce a recessive disease characterized by hypomagnesemia, hypermagnesuria, hypercalciuria, and nephrocalcinosis. Mutations in the gene encoding TRPM6 induce profound hypomagnesemia by impaired intestinal Mg^{2+} absorption and renal Mg^{2+} wasting, with secondary hypocalcemia.³⁵

In the distal convoluted tubule, inactivating mutations of the gene encoding the thiazide-sensitive, electroneutral Na^+-Cl^- cotransporter (NCCT) in Gitelman's syndrome are also responsible for selective renal magnesium wasting and hypomagnesemia.

Hypomagnesemia associated with inappropriate magnesuria has been reported in an autosomal dominant, isolated familial hypomagnesemia syndrome, which appears to be due to misrouting of the $Na^+, K^+-ATPase$ γ subunit.³⁶

Clinical Manifestations

Specific clinical manifestations of hypomagnesemia may be difficult to appreciate because of concomitant hypocalcemia and hypokalemia. The main clinical manifestations of moderate to severe magnesium depletion include general weakness and neuromuscular hyperexcitability with hyperreflexia, carpopedal spasm, seizure, tremor, and, rarely, tetany. Cardiac findings include a prolonged QT interval and ST depression. There is a predisposition to ventricular arrhythmias and potentiation of digoxin toxicity. The role of magnesium deficiency in the clinical development of seizures and cardiac arrhythmias is demonstrated by the treatment of these conditions with magnesium. In one large study of mothers with pregnancy-related hypertension, intravenous magnesium administration was more effective than phenytoin for prevention of eclamptic seizures. In several studies of patients with acute myocardial infarction and hypomagnesemia, magnesium repletion reduced the frequency of cardiac arrhythmias.

Magnesium deficiency can also be associated with hypocalcemia (decreased PTH release and end-organ responsiveness) and hypokalemia (urinary loss). In addition, intracellular K^+ is frequently decreased. Magnesium deficit constitutes a cardiovascular risk factor and also a risk factor in pregnancy for the mother and the fetus.

The diagnosis of moderate degrees of magnesium deficiency is not easy because clinical manifestations may be absent and blood Mg^{2+} levels may not reflect the state of body magnesium. Severe magnesium deficits, however, are associated with hypomagnesemia.

Treatment

Magnesium deficiency is managed with the administration of magnesium salts. Magnesium sulfate is generally used for

parenteral therapy (1500 to 3000 mg [150 to 300 mg elemental magnesium] per day). A variety of magnesium salts are available for oral administration, including oxide, hydroxide, sulfate, lactate, chloride, carbonate, and pidolate. Oral magnesium salts often are not well tolerated. All of them may induce gastrointestinal intolerance, in particular diarrhea.

Normal Acid-Base Balance

Biff F. Palmer, Robert J. Alpern

DEFINITION

The acid-base status of the body is carefully regulated to maintain the arterial pH between 7.35 and 7.45 and the intracellular pH between 7.0 and 7.3. This regulation occurs in the setting of continuous production of acidic metabolites and is accomplished by intracellular and extracellular buffering processes in conjunction with respiratory and renal regulatory mechanisms. This chapter reviews the normal physiology of acid-base homeostasis.

NET ACID PRODUCTION

Both acid and alkali are generated from the diet. Lipid and carbohydrate metabolism result in production of CO_2 , a volatile acid, at the rate of approximately 15,000 mmol/day. Protein metabolism yields amino acids, which can be metabolized to form nonvolatile acid and alkali. Amino acids such as lysine and arginine yield acid on metabolism, whereas the amino acids glutamate and aspartate and organic anions such as acetate and citrate generate alkali. Sulfur-containing amino acids (methionine and cysteine) are metabolized to sulfuric acid (H_2SO_4), and organophosphates are metabolized to phosphoric acid (H_3PO_4). In general, animal foods are high in proteins and organophosphates, thereby providing a net acid diet; plant foods are higher in organic anions and provide a net alkaline load. In addition to acid and alkali generated from the diet, there is a small daily production of organic acids including acetic acid, lactic acid, and pyruvic acid. Last, a small amount of acid is generated by the excretion of alkali into the stool. Under normal circumstances, daily net nonvolatile acid production is approximately 1 mmol hydrogen ions (H^+) per kilogram of body weight.

BUFFER SYSTEMS IN REGULATION OF pH

Intracellular and extracellular buffer systems minimize the change in pH during the addition of acid or base equivalents but do not remove acid or alkali from the body. The most important buffer system is that of the bicarbonate ion and carbon dioxide (HCO_3^- - CO_2). In this system, $[\text{CO}_2]$ is maintained at a constant level set by respiratory control. Addition of acid (HA) leads to conversion of HCO_3^- to CO_2 according to the reaction $\text{HA} + \text{NaHCO}_3 \rightarrow \text{NaA} + \text{H}_2\text{O} + \text{CO}_2$.

HCO_3^- is consumed, but $[\text{CO}_2]$ does not change because this is maintained by respiration. The net result is that the acid load has been buffered and pH changes are minimal.

Whereas the HCO_3^- - CO_2 buffer system is the most important of the buffers in extracellular fluid (ECF), other buffers such

as plasma proteins and phosphate ions also participate in the maintenance of a stable pH. During metabolic acidosis, the skeleton becomes a major buffer source as acid-induced dissolution of bone apatite releases alkaline Ca^{2+} salts and HCO_3^- into the ECF. With chronic metabolic acidosis, this can result in osteomalacia and osteoporosis. The calcium released can result in hypercalciuria and an increased likelihood of renal stones. Within the intracellular compartment, pH is maintained by intracellular buffers such as hemoglobin, cellular proteins, organophosphate complexes, and HCO_3^- as well as by the H^+ - HCO_3^- transport mechanisms that serve to transport acid and alkali in and out of the cell.

RESPIRATORY SYSTEM IN REGULATION OF pH

Removal of acid or alkali from the body is accomplished by the lungs and kidneys. The lungs regulate the CO_2 tension, and the kidneys regulate the serum HCO_3^- concentration. Although the HCO_3^- - CO_2 buffer system is not the only buffer system, all extracellular buffer systems are in equilibrium. Because the serum HCO_3^- concentration is far greater than that of other buffers, changes in the HCO_3^- - CO_2 buffer pair can easily titrate other buffer systems and thus set pH. The Henderson-Hasselbalch equation explains how the lungs and kidneys function in concert:

$$\text{pH} = 6.1 + \log \left[\frac{[\text{HCO}_3^-]}{(0.03 \times \text{Paco}_2)} \right]$$

As can be seen, pH is determined by the ratio of HCO_3^- to CO_2 . Conditions associated with similar fractional changes in the concentrations of HCO_3^- and CO_2 , such as when both are halved, will not change blood pH.

The lungs defend pH by altering alveolar ventilation, which alters the CO_2 excretion rate and thereby controls the Paco_2 of body fluids. Systemic acidosis stimulates the respiratory center, resulting in increased respiratory drive that lowers the Paco_2 . As a result, the fall in blood pH is less than would have occurred in the absence of respiratory compensation. If the fractional change in CO_2 tension were similar to that in serum HCO_3^- concentration, blood pH would not change. However, respiratory compensation rarely normalizes blood pH, and thus the fractional change in CO_2 tension is less than the change in the serum HCO_3^- concentration. Quantitatively, the normal respiratory response in metabolic acidosis is a 1.2 mm Hg decrease in Paco_2 for every 1 mmol/L decrease in HCO_3^- ; the increase in Paco_2 in response to metabolic alkalosis averages 0.7 mm Hg for every 1 mmol/L increase in HCO_3^- above baseline.¹

RENAL REGULATION OF pH

Buffer systems and respiratory excretion of CO_2 help maintain normal acid-base balance, but the kidneys provide a critical role in acid-base homeostasis. The kidneys normally generate sufficient net acid excretion to balance nonvolatile acid produced from normal metabolism. Net acid excretion (NAE) has three components, titratable acids, ammonium, and bicarbonate, and is calculated by the following formula:

$$\text{NAE} = U_{\text{Am}}V + U_{\text{TA}}V - U_{\text{HCO}_3^-}V$$

where $U_{\text{Am}}V$ is the rate of NH_4^+ excretion, $U_{\text{TA}}V$ is the rate of titratable acid excretion, and $U_{\text{HCO}_3^-}V$ is the rate of HCO_3^- excretion. Under basal conditions, approximately 40% of net acid excretion is in the form of titratable acids and 60% is in the form of ammonia; urinary bicarbonate concentrations and excretion are essentially zero under normal conditions. When acid production increases, the increase in acid excretion is almost entirely due to an increase in excretion of NH_4^+ .

RENAL TRANSPORT MECHANISMS OF HYDROGEN AND BICARBONATE IONS

Glomerulus

The glomerulus is not normally considered as participating in acid-base regulation. However, the glomerulus filters an amount of HCO_3^- equivalent to the serum HCO_3^- concentration multiplied by the glomerular filtration rate (GFR). Under normal circumstances, the filtered load of HCO_3^- averages approximately 4000 mmol/day. Normal acid-base homeostasis requires both the reabsorption of this filtered bicarbonate and the generation of “new” bicarbonate; the latter replenishes bicarbonate and other alkaline buffers consumed in the process of titrating endogenous acid production. From the standpoint of prevention of or correction of acidosis, GFR is not regulated by alterations in acid or base and therefore does not contribute to acid-base homeostasis.

Proximal Tubule

The proximal tubule reabsorbs approximately 80% of the filtered load of HCO_3^- . In addition, by titration of luminal pH from 7.4 down to approximately 6.7, the majority of phosphate, the major form of titratable acid, is titrated to its acid form. Lastly, ammonia synthesis occurs in the proximal tubule.

Figure 11.1 shows the acid-base transport mechanisms of the proximal tubule cell. HCO_3^- absorption from the tubular lumen is mediated by H^+ secretion across the membrane.² This H^+ secretion is active in that the electrochemical gradient favors H^+ movement from lumen to cell. Two mechanisms mediate active apical H^+ secretion. Approximately two thirds occurs through the apical membrane $\text{Na}^+\text{-H}^+$ antiporter NHE3.³ This protein uses the inward Na^+ gradient to drive H^+ secretion. The $\text{Na}^+\text{-H}^+$ exchanger has a 1:1 stoichiometry and is electroneutral. In parallel with the $\text{Na}^+\text{-H}^+$ antiporter, there is an apical membrane $\text{H}^+\text{-ATPase}$ that mediates approximately one third of basal proximal tubular HCO_3^- absorption.

Both of these H^+ transporters generate base in the cell, which must exit across the basolateral membrane to effect transepithelial transport. This primarily occurs through a basolateral $\text{Na}^+\text{-HCO}_3^-\text{-CO}_3^{2-}$ cotransporter. Because this protein transports the

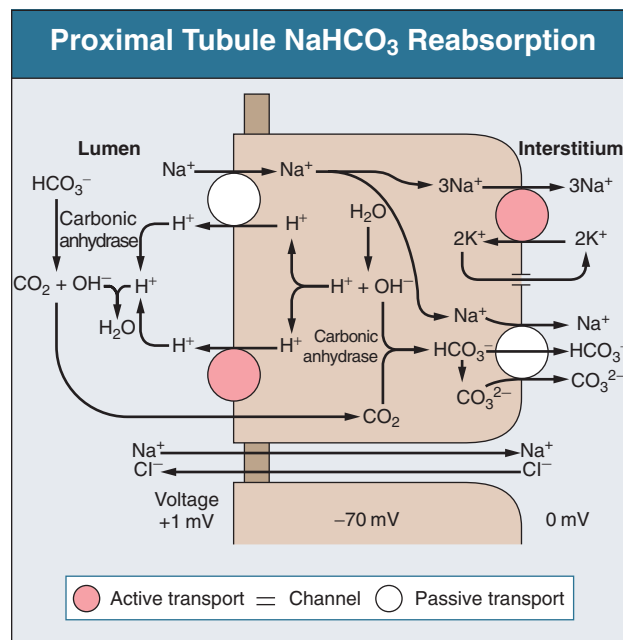

Figure 11.1 Proximal tubule NaHCO_3 reabsorption. The secretion of H^+ into the proximal tubule lumen involves a $\text{Na}^+\text{-H}^+$ antiporter and a $\text{H}^+\text{-ATPase}$. Apical membrane H^+ secretion generates OH^- , which reacts with CO_2 to form HCO_3^- and CO_3^{2-} , and these exit with a Na^+ on the basolateral membrane $\text{Na}^+\text{-HCO}_3^-\text{-CO}_3^{2-}$ cotransporter. The Na^+ absorbed by the $\text{Na}^+\text{-H}^+$ antiporter exits the cell on the basolateral membrane $\text{Na}^+\text{-HCO}_3^-\text{-CO}_3^{2-}$ cotransporter. The K^+ that enters the cell on the $\text{Na}^+\text{-HCO}_3^-\text{-CO}_3^{2-}$ cotransporter exits the cell on a basolateral membrane K^+ channel. Carbonic anhydrase catalyzes the conversion of HCO_3^- to CO_2 and OH^- in the lumen and the reverse reaction in the cell. Electrogenic H^+ secretion generates a small lumen-positive voltage that generates a current flow across the paracellular pathway.

equivalent of two net negative charges, the negative cell voltage generated by the basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$ provides a strong favorable driving force for base efflux. The Na^+ that is carried on this transporter is moved out of the cell energy free in that ATP is not required. The $\text{Na}^+\text{-3HCO}_3^-$ cotransporter NBC1, encoded by the gene *SLC4A4*, mediates the majority of proximal tubule basolateral base exit.⁴

Carbonic anhydrase is present in the proximal tubular cell cytoplasm and on the apical and basolateral membranes. Carbonic anhydrase has a number of functions in the proximal tubule. Apical membrane carbonic anhydrase allows secreted H^+ ions to react with luminal HCO_3^- , forming H_2CO_3 , which rapidly dissociates to $\text{CO}_2 + \text{H}_2\text{O}$. This CO_2 diffuses across the apical plasma membrane into the cell. There the process is reversed, with use of cytoplasmic carbonic anhydrase, generating intracellular H^+ and HCO_3^- . This H^+ “replenishes” the H^+ secreted across the apical membrane, resulting in net movement of the HCO_3^- from the luminal solution to the cell cytoplasm. The intracellular HCO_3^- is then secreted across the basolateral plasma membrane as described previously.

Thick Ascending Limb of the Loop of Henle

Tubular fluid arriving at the early distal tubule has a pH and serum HCO_3^- concentration similar to that in the late proximal tubule. Because there is significant water extraction in the loop of Henle, maintenance of a constant serum HCO_3^- concentration requires reabsorption of HCO_3^- . The majority of this HCO_3^- absorption occurs in the thick ascending limb

Figure 11.2 H^+ and HCO_3^- transport in the thick ascending limb. Apical H^+ secretion is mediated by a Na^+-H^+ antiporter. The low intracellular Na^+ concentration, maintained by the basolateral $\text{Na}^+,\text{K}^+-\text{ATPase}$, provides the primary driving force for the antiporter. Both $\text{Cl}^--\text{HCO}_3^-$ exchange and $\text{Na}^+-\text{HCO}_3^- - \text{CO}_3^{2-}$ cotransport mediate base exit across the basolateral membrane.

through mechanisms that are similar to those present in the proximal tubule (Fig. 11.2). The majority of apical membrane H^+ secretion is mediated by the Na^+-H^+ antiporter NHE3. As in the proximal tubule, the low intracellular Na^+ concentration maintained by the basolateral $\text{Na}^+,\text{K}^+-\text{ATPase}$ provides the primary driving force for the antiporter. Base efflux across the basolateral membrane is mediated by a $\text{Cl}^--\text{HCO}_3^-$ exchanger and a $\text{Na}^+-\text{HCO}_3^- - \text{CO}_3^{2-}$ cotransporter. These cells also possess a H^+-ATPase , but it is not clear what role it plays in acidification.

Distal Nephron

Approximately 80% of the filtered HCO_3^- is reabsorbed in the proximal tubule; most but not all of the remainder is absorbed in the thick ascending limb. One function of the distal nephron is to reabsorb the remaining 5% of filtered HCO_3^- . In addition, the distal nephron must secrete a quantity of H^+ equal to that generated systemically by metabolism to maintain acid-base balance.

The distal nephron is subdivided into several distinct portions that differ in their anatomy and acid secretory properties. Most of these segments transport H^+ and HCO_3^- into the luminal fluid, but the main segments appear to be in the collecting duct.⁵ The segments of the collecting duct include the cortical collecting duct, the outer medullary collecting duct, and the inner medullary collecting duct. There are two distinct cell types in the cortical collecting duct that can be distinguished histologically: the principal cell and the intercalated cell. The principal cell reabsorbs Na^+ and secretes K^+ and is discussed further later. Depending on chronic acid-base status, the cortical collecting duct is capable of either H^+ or HCO_3^- secretion. These functions are mediated by two types of intercalated cells: the acid-secreting

Figure 11.3 Secretion of H^+ in the α -intercalated cell. Secretion of H^+ into the lumen by a H^+-ATPase and a $\text{H}^+,\text{K}^+-\text{ATPase}$. Apical membrane H^+ secretion generates OH^- , which reacts with CO_2 to form HCO_3^- ; this exits across the basolateral membrane on a $\text{Cl}^--\text{HCO}_3^-$ exchanger. The Cl^- that enters the cell on the exchanger recycles across a basolateral membrane Cl^- channel. The K^+ that enters the cell on the $\text{H}^+,\text{K}^+-\text{ATPase}$ appears to be able either to recycle across the apical membrane or to exit across the basolateral membrane, depending on the potassium balance of the individual. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell. Electrogenic H^+ secretion generates a lumen-positive voltage that generates a current flow across the paracellular pathway.

α -intercalated cell and the base-secreting β -intercalated cell. Both types of intercalated cells are rich in carbonic anhydrase.

Reabsorption of HCO_3^- in the distal nephron is mediated by apical H^+ secretion by the α -intercalated cell. Two transporters secrete H^+ : a vacuolar H^+-ATPase and a $\text{H}^+,\text{K}^+-\text{ATPase}$ (Fig. 11.3). The vacuolar H^+-ATPase is an electrogenic pump related to the H^+ pump present within lysosomes, the Golgi apparatus, and endosomes. The $\text{H}^+,\text{K}^+-\text{ATPase}$ uses the energy derived from ATP hydrolysis to secrete H^+ into the lumen and to reabsorb K^+ in an electroneutral fashion. The activity of the $\text{H}^+,\text{K}^+-\text{ATPase}$ increases in K^+ depletion and thus provides a mechanism by which K^+ depletion enhances both collecting duct H^+ secretion and K^+ absorption.

Active H^+ secretion by the apical membrane generates intracellular base that must exit the basolateral membrane. A basolateral $\text{Cl}^--\text{HCO}_3^-$ exchanger is the mechanism by which this base exit occurs. The Cl^- that enters the cell in exchange for HCO_3^- exits the cell through a basolateral membrane Cl^- conductance channel (see Fig. 11.3).

The HCO_3^- -secreting β -intercalated cell is a mirror image of the α -intercalated cell (Fig. 11.4). It possesses a H^+-ATPase on the basolateral membrane, which mediates active H^+ extrusion. Alkali that is generated within the cell then exits on an apical membrane $\text{Cl}^--\text{HCO}_3^-$ exchanger. This $\text{Cl}^--\text{HCO}_3^-$ exchanger is distinct from the basolateral $\text{Cl}^--\text{HCO}_3^-$ exchanger present in the α -intercalated cell and functions as an anion exchanger or Cl^- channel in the luminal membrane of epithelial cells.⁶ The SLC26A4 protein (pendrin) is a family member that mediates

Figure 11.4 Bicarbonate secretion by the β -intercalated cell. Here H^+ is secreted into the interstitium by a H^+ -ATPase. The OH^- generated by basolateral membrane H^+ secretion reacts with CO_2 to form HCO_3^- , which exits across the apical membrane on a Cl^- - HCO_3^- exchanger. The Cl^- that enters the cell on the exchanger exits across a basolateral membrane Cl^- channel. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell.

apical Cl^- - HCO_3^- exchange in the β -intercalated cell of the kidney.

The other cortical collecting tubule cell type is the principal cell, and it too regulates acid-base transport, albeit indirectly. Principal cells mediate electrogenic Na^+ reabsorption that results in a net negative luminal charge (Fig. 11.5). The greater this negative charge is, the lesser the electrochemical gradient for electrogenic proton secretion and therefore the greater the rate of net proton secretion. Thus, factors that stimulate Na^+ reabsorption indirectly regulate the H^+ secretory rate.

The medullary collecting duct possesses mechanisms only for H^+ secretion. This H^+ secretion is mediated by α -intercalated cells but also by cells that appear morphologically distinct from intercalated cells yet are functionally similar.

Net Acid Excretion

For the kidney to generate net acid excretion, it must both reabsorb filtered HCO_3^- and excrete titratable acids and ammonia. Several weak acids, such as phosphate, creatinine, and uric acid, are filtered at the glomerulus and can buffer secreted protons. Of these, phosphate is the most important because of its favorable pK_a of 6.80 and its relatively high rate of urinary excretion (~25 to 30 mmol/day). However, the capacity of phosphate to buffer protons is maximized at a urine pH of 5.8, and acid-base disturbances do not, in general, induce substantial changes in urinary phosphate excretion. Other titratable acids, such as creatinine and uric acid, are limited by their lower excretion rates that are not dramatically changed in response to acid-base disturbances. As shown in Figure 11.6, titratable acid excretion is a minor component of the increase in net acid excretion in response to metabolic acidosis.

Ammonia Metabolism

Quantitatively, the most important component of net acid excretion is the $\text{NH}_3/\text{NH}_4^+$ system.⁷ Unlike for titratable acids, the

Figure 11.5 Transport of Na^+ in the principal cell of the cortical collecting duct. Electrogenic Na^+ absorption is mediated by a Na^+ channel. The Na^+ enters the cell across the apical membrane channel and exits the cell on the basolateral membrane Na^+ , K^+ -ATPase. The K^+ that enters the cell on the basolateral Na^+ , K^+ -ATPase can be secreted into the luminal fluid by an apical membrane K^+ channel. Electrogenic Na^+ absorption establishes a lumen-negative voltage that drives a paracellular current.

rate of ammonia production and excretion varies according to physiologic needs. Under normal circumstances, ammonia excretion accounts for approximately 60% of total net acid excretion, and in chronic metabolic acidosis, almost the entire increase in net acid excretion is due to increased ammonia metabolism. Ammonia metabolism involves an interplay between the proximal tubule, the thick ascending limb of the loop of Henle, and the collecting duct.

The proximal tubule is responsible for both ammonia production and luminal secretion. Ammonia is synthesized in the proximal tubule predominantly from glutamine metabolism through enzymatic processes in which phosphoenolpyruvate carboxylase and phosphate-dependent glutaminase are the rate-limiting steps. This results in production of two NH_4^+ and two HCO_3^- ions from each glutamine ion. Ammonia is then preferentially secreted into the lumen. The primary mechanism for this luminal secretion appears to be NH_4^+ transport by the apical Na^+ - H^+ antiporter NHE3.

Metabolic acidosis increases the mobilization of glutamine from skeletal muscle and intestinal cells. Glutamine is preferentially taken up by the proximal tubular cell through the Na^+ - and H^+ -dependent glutamine transporter SNAT3. This transporter is a member of the *SCL38* gene family of Na^+ -coupled neutral amino acid transporters. SNAT3 expression increases several-fold in metabolic acidosis, and it is preferentially expressed on the cell's basolateral surface, where it is poised for glutamine uptake.⁸ The increase in plasma glucocorticoids that typically accompanies metabolic acidosis plays a role in this transporter's upregulation.⁹ Metabolic acidosis also causes increased expression and activity of phosphate-activated glutaminase and glutamate dehydrogenase.

Figure 11.6 Changes in net acid excretion in response to chronic metabolic acidosis. Chronic metabolic acidosis increases net acid excretion dramatically during several days. This figure shows quantitatively the increases in the two major components of net acid excretion: titratable acids and ammonia. Titratable acid excretion increases slightly and predominantly in the first 24 to 48 hours. In contrast, urinary ammonia excretion progressively increases during a period of 7 days and is responsible for the majority of the increase in net acid excretion in chronic metabolic acidosis. (Data plotted are redrawn from original data of reference 10.)

Most of the ammonia that leaves the proximal tubule does not return to the distal tubule. Thus, there is transport of ammonia out of the loop of Henle. This transport appears to occur predominantly in the thick ascending limb of the loop of Henle and is mediated by at least three mechanisms. First, the lumen-positive voltage provides a driving force for passive paracellular NH_4^+ transport out of the thick ascending limb. Second, NH_4^+ can be transported out of the lumen by the furosemide-sensitive $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ transporter. Last, NH_4^+ can leave the lumen across the apical membrane K^+ channel of the thick ascending limb cell. There is little information as to how NH_4^+ would then leave the cell across the basolateral membrane.

Finally, ammonia is secreted by the collecting duct. Although the traditional thought was that $\text{NH}_3/\text{NH}_4^+$ then enters the collecting duct by nonionic diffusion driven by the acid luminal pH, increasing evidence suggests that the nonerythroid glycoproteins Rhbg and Rhcg may be involved in collecting duct ammonia secretion.^{11,12}

On the basis of the preceding discussion, ammonia excretion can be regulated by three mechanisms. First, ammonia synthesis in the proximal tubule can be regulated. Chronic acidosis and hypokalemia increase ammonia synthesis, whereas hyperkalemia suppresses ammonia synthesis. Second, ammonia delivery from the proximal tubule to the medullary interstitium can be regulated. In particular, chronic metabolic acidosis increases expression of both NHE3 and the loop of Henle $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter. Hyperkalemia can inhibit NH_4^+ reabsorption from the thick ascending limb. This may explain the low urinary $[\text{NH}_4^+]$ found in hyperkalemic distal renal tubular acidosis (in addition to decreased synthesis of ammonia by hyperkalemia). In addition, any interstitial renal disease that destroys renal

medullary anatomy may decrease medullary interstitial $[\text{NH}_3/\text{NH}_4^+]$. Last, mechanisms that regulate collecting duct H^+ secretion or ammonia transporter expression can regulate ammonia entry into the collecting duct and excretion. Importantly, the primary mechanisms require synthesis of new proteins to increase both ammonia production and transport. Accordingly, changes in ammonia excretion may be delayed, and the maximal renal response to chronic metabolic acidosis requires 4 to 7 days.

REGULATION OF RENAL ACIDIFICATION

The regulation of acid-base balance requires an integrated system that precisely regulates proximal tubular $\text{H}^+\text{-HCO}_3^-$ transport, distal nephron $\text{H}^+\text{-HCO}_3^-$ transport, and ammonia synthesis and transport.

Blood pH

The regulation of acid-base balance requires that net H^+ excretion increase in states of acidosis and decrease in states of alkalosis. This form of regulation involves both acute and chronic mechanisms. In the proximal tubule, acute decreases in blood pH increase the rate of HCO_3^- absorption, and acute increases in blood pH inhibit HCO_3^- absorption. These alterations in the rate of HCO_3^- absorption occur whether the change in pH is the result of changes in Paco_2 or serum HCO_3^- concentration. Similarly, in the collecting duct, acute changes in peritubular serum HCO_3^- concentration and pH regulate the rate of H^+ secretion.

In addition to acute regulation, mechanisms exist for chronic regulation. Chronic acidosis or alkalosis leads to parallel changes in the activities of the proximal tubule apical membrane $\text{Na}^+\text{-H}^+$ antiporter and basolateral membrane $\text{Na}^+\text{-HCO}_3^- \text{-CO}_3^{2-}$ cotransporter. Metabolic acidosis acutely increases the kinetic activity of NHE3 through direct pH effects and by phosphorylation; chronic acidosis increases the number of NHE3 transporters.^{13,14} In addition, chronic acidosis increases proximal tubular ammonia synthesis by increasing the activities of the enzymes involved in ammonia metabolism.

The cortical collecting duct is also modified by chronic acid-base changes. Long-term increases in dietary acid lead to an increase in H^+ secretion, whereas long-term increases in dietary alkali lead to an increased capacity for HCO_3^- secretion.¹⁵ This effect is mediated by changes in the relative number of α - and β -intercalated cells. For example, during metabolic acidosis, the number of α -intercalated cells increases while the number of β -intercalated cells decreases without a change in the total number of intercalated cells. Recent evidence suggests that the extracellular protein hensen may be involved in the switch between the predominant intercalated cell type.¹⁶

Mineralocorticoids, Distal Sodium Delivery, and Extracellular Fluid Volume

Mineralocorticoid hormones are key regulators of distal nephron and collecting duct H^+ secretion. Two mechanisms appear to be involved. First, mineralocorticoid hormone stimulates Na^+ absorption in principal cells of the cortical collecting duct (see Fig. 11.5). This leads to a more lumen-negative voltage that then stimulates H^+ secretion. This mechanism is indirect in that it requires the presence of Na^+ and of Na^+ transport.

A second mechanism is the direct activation of H^+ secretion by mineralocorticoids. This effect is chronic, requiring long

exposure, and involves parallel increases in apical membrane H^+ -ATPase and basolateral membrane Cl^- - HCO_3^- exchanger activity.

Plasma Volume

Changes in plasma volume have important effects on acid-base homeostasis. This effect appears to be related to a number of factors. First, volume contraction is associated with a decreased GFR that lowers the filtered load of HCO_3^- and decreases the load placed on the tubules to maintain net acid excretion. Volume contraction also acutely decreases the paracellular permeability of the proximal tubule. This will decrease HCO_3^- backleak around cells, thereby increasing net bicarbonate reabsorption by the proximal tubule. Third, chronic volume contraction is associated with an adaptive increase in the activity of the proximal tubule apical membrane Na^+ - H^+ antiporter NHE3. Because this transporter contributes to both $NaHCO_3$ and $NaCl$ absorption, both of these capacities will be increased with chronic volume contraction. Last, volume contraction limits distal delivery of chloride. In the presence of chronic metabolic alkalosis, the cortical collecting duct is poised for HCO_3^- secretion. However, collecting duct HCO_3^- secretion requires luminal Cl^- and is inhibited by Cl^- deficiency.

Potassium

Potassium deficiency is associated with an increase in renal net acid excretion. This effect is multifactorial. First, chronic K^+ deficiency increases the proximal tubule apical membrane Na^+ - H^+ antiporter and basolateral membrane Na^+ - HCO_3^- - CO_3^{2-} cotransporter activities. This effect is similar to that seen with chronic acidosis and may be due to intracellular acidosis. Chronic K^+ deficiency also increases proximal tubular ammonia production. Last, chronic K^+ deficiency leads to an increase in collecting duct H^+ secretion. This appears to be related to increased activity of the apical membrane H^+ , K^+ -ATPase. Such an effect increases the rate of H^+ secretion and the rate of K^+ reabsorption in the collecting duct. Finally, ammonia, whose production is stimulated by hypokalemia, has direct effects that stimulate collecting duct H^+ secretion. Counterbalancing these effects is that K^+ deficiency decreases aldosterone secretion, which can inhibit distal acidification. Thus, in normal individuals, the net effect of K^+ deficiency is typically a minor change in acid-base balance. However, in those in whom mineralocorticoid secretion is non-suppressible (e.g., hyperaldosteronism, Cushing's syndrome), K^+ deficiency can markedly stimulate renal acidification and cause profound metabolic alkalosis.

Hyperkalemia appears to have opposite effects on renal acidification. The most notable effect of hyperkalemia is inhibition of ammonia synthesis in the proximal tubule and ammonia absorption in the loop of Henle, thereby resulting in inappropriately low levels of urinary ammonia excretion. This contributes to the metabolic acidosis seen in patients with hyperkalemic distal (type 4) renal tubular acidosis.

Metabolic Acidosis

Biff F. Palmer, Robert J. Alpern

DEFINITION

Metabolic acidosis is defined as a low arterial blood pH in conjunction with a reduced serum HCO_3^- concentration. Respiratory compensation results in a decrease in Paco_2 . A low serum HCO_3^- concentration alone is not diagnostic of metabolic acidosis because it also results from the renal compensation to chronic respiratory alkalosis. Measurement of the arterial pH differentiates between these two possibilities. Figure 12.1 shows the expected compensatory responses for metabolic and respiratory acid-base disorders.¹

After the diagnosis of metabolic acidosis is confirmed, the first step in the examination of metabolic acidosis is to calculate the serum anion gap. The anion gap is equal to the difference between the plasma concentrations of the major cation (Na^+) and the major measured anions (Cl^- and HCO_3^-) and is given by the following formula:

$$\text{anion gap} = [\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

In healthy individuals, the normal value of the anion gap is approximately 12 ± 2 mmol/l. Because many of the unmeasured anions consist of albumin, the normal anion gap is decreased by approximately 4 mmol/l for each 1 g/dl decrease in the serum albumin concentration below normal. The total number of cations must equal the total number of anions, so a decrease in the serum HCO_3^- concentration must be offset by an increase in the concentration of other anions. If the anion accompanying excess H^+ is Cl^- , the decrease in the serum HCO_3^- concentration is matched by an equal increase in the serum Cl^- concentration. This acidosis is classified as a “normal anion gap” or a “non-anion gap” or a hyperchloremic metabolic acidosis. By contrast, if excess H^+ is accompanied by an anion other than Cl^- , the decreased HCO_3^- is balanced by an increase in the concentration of the unmeasured anion. The Cl^- concentration remains the same. In this setting, the acidosis is said to be a “high anion gap” or “anion gap” metabolic acidosis.

The normal value for the anion gap has tended to fall over time because of changes in how serum Na^+ and Cl^- are measured.² Flame photometry for Na^+ measurement and a colorimetric assay for Cl^- have been replaced by the use of ion-selective electrodes, with which the serum Na^+ values have largely remained the same, whereas the serum Cl^- values have tended to be higher. As a result, the normal value for the anion gap has decreased to as low as 6 mmol/l in some reports. Recognizing this change, some laboratories have adjusted the calibration set point for Cl^- to return the normal value for the anion gap to the 12 ± 2 mmol/l range. It is important for the clinician to be aware that the average anion gap and range of normal values will vary among different facilities.

Figure 12.2 provides a recommended approach to a patient with metabolic acidosis and lists the common causes of metabolic acidosis according to the anion gap.

NON-ANION GAP (NORMAL ANION GAP) METABOLIC ACIDOSIS

A non-anion gap metabolic acidosis can result from either renal or extrarenal causes. Renal causes of metabolic acidosis occur when renal bicarbonate generation, which results from net acid excretion, does not balance the loss of bicarbonate and other alkali buffers consumed in the buffering of normal endogenous acid production. This failure of net acid excretion is termed renal tubular acidosis (RTA). Extrarenal causes occur when exogenous acid loads, endogenous acid production, or endogenous bicarbonate losses are elevated and exceed renal net acid excretion. The most common extrarenal cause of non-anion gap metabolic acidosis is chronic diarrhea.

Renal and extrarenal causes of metabolic acidosis can be distinguished by measuring urinary ammonia excretion.³ The primary response of the kidney to metabolic acidosis is to increase urinary ammonia excretion, each millimole of urinary ammonia excreted resulting in the generation of 1 mmol of “new” bicarbonate. Thus, renal causes of metabolic acidosis are characterized by low urinary ammonia excretion rates. In contrast, in extrarenal metabolic acidosis, urinary ammonia excretion is elevated. Because most laboratories do not measure urinary ammonia, one can indirectly assess ammonia excretion by measuring the urinary anion gap (UAG):

$$\text{UAG} = (U_{\text{Na}^+} + U_{\text{K}^+}) - U_{\text{Cl}^-}$$

The UAG is normally a positive value, ranging from +30 to +50 mmol/l. A negative value for the UAG suggests increased renal excretion of an unmeasured cation (i.e., a cation other than Na^+ or K^+). One such cation is NH_4^+ . With chronic metabolic acidosis due to extrarenal causes, urinary ammonia concentrations, in the form of NH_4Cl , can reach 200 to 300 mmol/l. As a result, the measured cation concentration will be less than the measured anion concentration, which includes the increased urinary Cl^- , and the UAG will be less than zero and frequently less than -20 mmol/l.

The UAG only indirectly reflects the urinary ammonia concentration and, if other unmeasured ions are excreted, can give misleading results. Examples include diabetic ketoacidosis, associated with substantial urinary excretion of sodium keto acid salts, and toluene exposure (discussed later), associated with increased urinary excretion of sodium hippurate and sodium

Compensation in Acid-Base Disorders	
Acute respiratory acidosis	<ul style="list-style-type: none"> For every 10 mm Hg rise in PCO_2 the HCO_3^- increases by 1 mmol/l

Acute respiratory alkalosis	<ul style="list-style-type: none"> For every 10 mm Hg fall in PCO_2 the HCO_3^- decreases by 2 mmol/l
Chronic respiratory alkalosis	<ul style="list-style-type: none"> For every 10 mm Hg decrease in PCO_2 the HCO_3^- decreases by 5 mmol/l
Metabolic acidosis	<ul style="list-style-type: none"> 1.2 mm Hg decrease in PCO_2 for each 1 mmol/l fall in HCO_3^- $\text{PCO}_2 = \text{HCO}_3^- + 15$ $\text{PCO}_2 = \text{last digits of pH}$
Metabolic alkalosis	<ul style="list-style-type: none"> PCO_2 increases by 0.7 for each mmol/l HCO_3^-

Figure 12.1 Expected compensatory responses to acid-base disorders.

benzoate. In these settings, the UAG value may remain positive despite an appropriate increase in urinary ammonia excretion because of the increased urinary excretion of Na^+ acid-anion salts. In most cases, these conditions are associated with an elevated anion gap metabolic acidosis, not a non-anion gap metabolic acidosis, and thus are easily distinguishable from diarrhea-induced metabolic acidosis.

Urine pH, in contrast to the UAG, does not reliably differentiate acidosis of renal origin from that of extrarenal origin. For example, an acid urine pH does not necessarily indicate an appropriate increase in net acid excretion. If renal ammonia metabolism is inhibited, as occurs with chronic hyperkalemia, there is decreased ammonia available in the distal nephron to serve as a buffer, and small amounts of distal H^+ secretion can lead to a significant urine acidification. In this setting, the urine pH is acid, but net acid excretion is low because of the low ammonia excretion. Similarly, alkaline urine does not necessarily imply a renal acidification defect. In conditions in which ammonia metabolism is stimulated, distal H^+ secretion can be massive and yet the urine remains relatively alkaline because of the buffering effects of ammonia.

Metabolic Acidosis of Renal Origin

An overall approach for workup of metabolic acidosis of renal origin is shown in Figure 12.3.

Proximal Renal Tubular Acidosis (Type 2)

Normally 80% to 90% of the filtered load of HCO_3^- is reabsorbed in the proximal tubule. In proximal RTA, the proximal tubule has a decreased capacity to reabsorb filtered bicarbonate. When serum bicarbonate concentration is normal or nearly normal, the amount of bicarbonate filtered by the glomerulus exceeds proximal tubule bicarbonate reabsorptive capacity. When this happens, there is increased bicarbonate delivery to the loop of Henle and distal nephron that exceeds their capacity

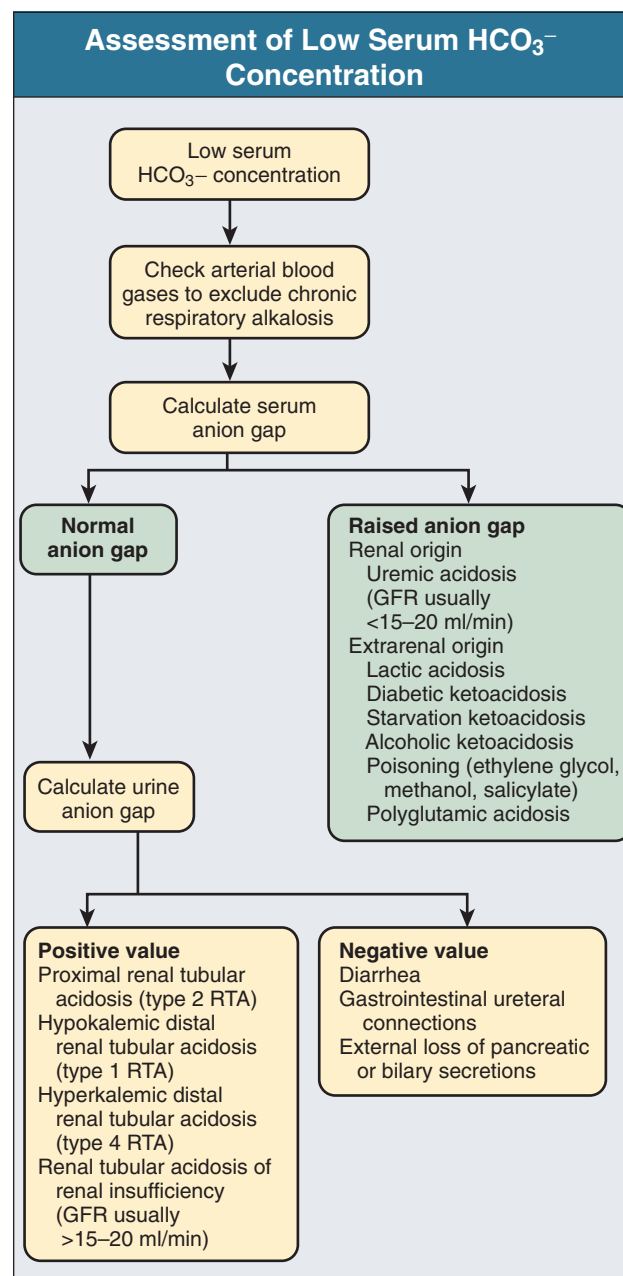

Figure 12.2 Approach to the patient with a low serum HCO_3^- concentration.

to reabsorb bicarbonate. As a result, some filtered bicarbonate appears in the urine. The net effect is that the serum HCO_3^- concentration decreases. Eventually, the filtered bicarbonate load decreases to the point at which the proximal tubule is able to reabsorb sufficient filtered bicarbonate that the bicarbonate load to the loop of Henle and the distal nephron is within their reabsorptive capacity. When this process occurs, no further bicarbonate is lost in the urine, net acid excretion normalizes, and a new steady-state serum bicarbonate concentration develops, albeit at a lower than normal level.

Hypokalemia is present in proximal RTA. Renal NaHCO_3 losses lead to intravascular volume depletion, which in turn activates the renin-angiotensin-aldosterone system. Distal Na^+ delivery is increased as a result of the impaired proximal reabsorption of NaHCO_3 . Because of the associated hyperaldoste-

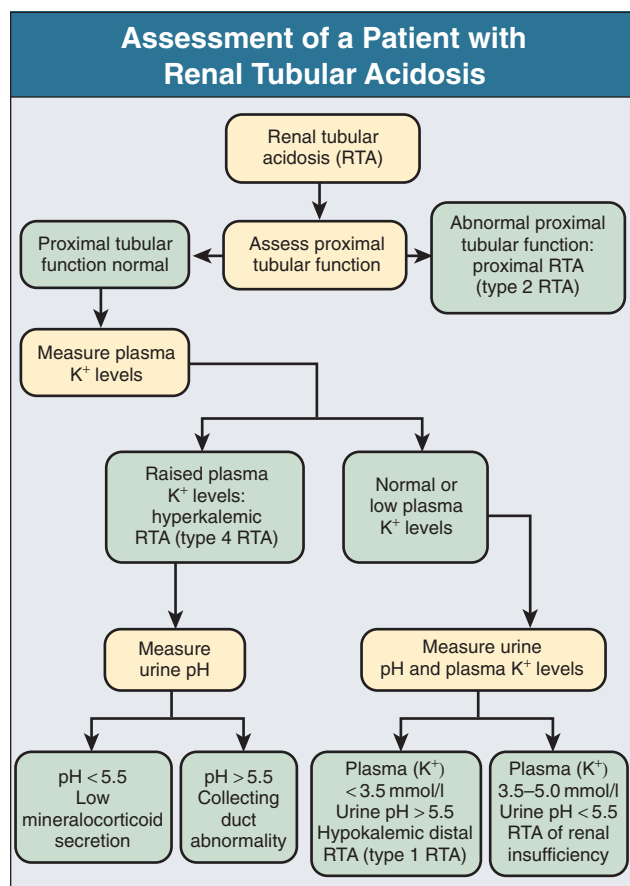

Figure 12.3 Approach to the patient with renal tubular acidosis (RTA).

ronism and increased distal nephron Na^+ reabsorption, there is increased K^+ secretion. The net result is renal potassium wasting and the development of hypokalemia. In the steady state, when virtually all the filtered HCO_3^- is reabsorbed in the proximal and distal nephron, renal potassium wasting is less and the degree of hypokalemia tends to be mild.

Proximal RTA may occur as an isolated defect in acidification, but it typically occurs in the setting of widespread proximal tubule dysfunction (Fanconi syndrome). In addition to decreased HCO_3^- reabsorption, patients with the Fanconi syndrome have impaired reabsorption of glucose, phosphate, uric acid, amino acids, and low-molecular-weight proteins. Various inherited and acquired disorders have been associated with the development of Fanconi syndrome and proximal RTA (Fig. 12.4). The most common inherited cause in children is cystinosis (see Chapter 48). Most adults with Fanconi syndrome have an acquired condition that is related to an underlying dysproteinemic condition, such as multiple myeloma.

Skeletal abnormalities are common in these patients. Osteomalacia can develop as a result of chronic hypophosphatemia due to renal phosphate wasting if Fanconi syndrome is present. These patients may also have a deficiency in the active form of vitamin D because of an inability to convert 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D in the proximal tubule.

In contrast to distal RTA, proximal RTA is not associated with nephrolithiasis or nephrocalcinosis. One exception is the use of topiramate,^{4,5} an antiepileptic drug that is increasingly used to treat a variety of neurologic and metabolic disorders. The drug exerts an inhibitory effect on renal carbonic anhydrase

activity, resulting in a proximal acidification defect similar to that observed with acetazolamide. Use of the drug also is associated with hypocitraturia, hypercalciuria, and elevated urine pH, leading to an increased risk of kidney stone disease.

Proximal RTA should be suspected in a patient with a normal anion gap acidosis and hypokalemia who has an intact ability to acidify the urine to below 5.5 while in a steady state.⁶ Proximal tubular dysfunction, such as euglycemic glycosuria, hypophosphatemia, hypouricemia, and mild proteinuria, helps support this diagnosis. The UAG is greater than zero, indicating the lack of increase in net acid excretion.

Treatment of proximal RTA is difficult. Administration of alkali increases the serum bicarbonate concentration, which increases urinary bicarbonate losses and thereby minimizes subsequent increases in the serum bicarbonate concentration. Moreover, the increased distal sodium load, in combination with increased circulating plasma aldosterone, results in increased renal potassium wasting and worsening hypokalemia. As a result, substantial amounts of alkali, often in the form of a potassium salt, such as potassium citrate, are required to prevent worsening hypokalemia. Children with proximal RTA should be

aggressively treated to normalize their serum bicarbonate concentration to minimize growth retardation. These children may require large amounts of alkali therapy, typically 5 to 15 mmol/kg per day.

Adults with proximal RTA are frequently not treated as aggressively as children are because of the lack of systemic metabolic abnormalities or bone disease. Many clinicians administer alkali therapy if the serum bicarbonate concentration is less than 18 mmol/L to prevent severe acidosis. Whether more aggressive therapy to normalize the serum bicarbonate concentration is beneficial remains unknown. However, the large amounts of alkali required, approximately 700 to 1000 mmol/day for a 70-kg individual, makes this approach problematic.

Hypokalemic Distal Renal Tubular Acidosis (Type 1)

In contrast to proximal RTA, patients with distal RTA are unable to acidify their urine, either under basal conditions or in response to metabolic acidosis.^{7,8} This disorder results from a reduction in net H^+ secretion in the distal nephron, which leads to continued urinary bicarbonate losses and prevents urinary acidification, thereby minimizing titratable acid excretion and urinary ammonia excretion. As a result, these patients are unable to match net acid excretion to endogenous acid production, and acid accumulation ensues. The subsequent metabolic acidosis stimulates reabsorption of bone matrix to release the calcium alkali salts present in bone. During prolonged periods, this can result in progressive osteopenia in adults and in osteomalacia in children.

Distal RTA can be caused by either impaired H^+ secretion (secretory defect) or an abnormally permeable distal tubule, resulting in increased backleak of normally secreted H^+ (gradient defect); it may be genetic or acquired. Certain medications, especially amphotericin, result in increased backleak of protons across the apical plasma membrane, thereby leading to a gradient defect form of distal RTA.

For patients with a secretory defect, the inability to acidify the urine below pH 5.5 results from abnormalities in any of the proteins involved in collecting duct H^+ secretion. Some patients may have an isolated defect in the H^+, K^+ -ATPase that impairs H^+ secretion and K^+ reabsorption.⁹ A defect confined to the vacuolar H^+ -ATPase also results in renal potassium wasting.¹⁰ The development of systemic acidosis tends to diminish net proximal fluid reabsorption with an increase in distal delivery, resulting in volume contraction and activation of the renin-aldosterone system. Increased distal Na^+ delivery coupled to increased circulating levels of aldosterone then leads to increased renal K^+ secretion. Defects in the basolateral anion exchanger (AE1) can also cause distal RTA. In this case, the lack of basolateral HCO_3^- exit leads to intracellular alkalinization, which inhibits apical proton secretion.

Patients with distal RTA have low ammonia secretion rates. The decreased secretion is caused by the failure to trap ammonia in the tubular lumen of the collecting duct as a result of the inability to lower luminal fluid pH. In addition, there is often impaired medullary transfer of ammonia because of interstitial disease. Interstitial disease is frequently present in such patients through an associated underlying disease or as a result of nephrocalcinosis or hypokalemia-induced interstitial fibrosis.

In contrast to proximal RTA, nephrolithiasis and nephrocalcinosis are common.¹¹ Urinary Ca^{2+} excretion is high secondary to acidosis-induced bone mineral dissolution. Luminal alkalization also inhibits calcium reabsorption, resulting in further increases in urinary calcium excretion.¹² Calcium phosphate solubility is also markedly lowered at alkaline pH, and calcium

Figure 12.5 Causes of hypokalemic distal (type 1) renal tubular acidosis (RTA).

phosphate stone formation is accelerated. Stone formation is further enhanced as a result of low urinary citrate excretion. Citrate is metabolized to HCO_3^- , and its renal reabsorption is stimulated by metabolic acidosis, thereby minimizing the severity of metabolic acidosis. Urinary citrate also chelates urinary calcium, thereby decreasing ionized calcium concentrations. Accordingly, the decreased citrate excretion that occurs in chronic metabolic acidosis due to distal RTA further contributes to both nephrolithiasis and nephrocalcinosis.

Distal RTA may be a primary disorder, either idiopathic or inherited, but it most commonly occurs in association with a systemic disease, of which one of the most common is Sjögren's syndrome (Fig. 12.5). Hypergammaglobulinemic states as well as drugs and toxins may also cause this disorder.

A common cause of acquired distal RTA is glue sniffing. Inhalation of toluene from the fumes of model glue, spray paint, and paint thinners can give rise to hypokalemic normal gap acidosis through multiple mechanisms. First, toluene inhibits collecting duct proton secretion. Second, metabolism of toluene produces the organic acids hippuric and benzoic acid. These are buffered by sodium bicarbonate, resulting in metabolic acidosis and the production of sodium hippurate and sodium benzoate. If plasma volume is normal, these salts are rapidly excreted in the urine, and a non-anion gap metabolic acidosis develops. If plasma volume is decreased, urinary excretion is limited, they accumulate, and an anion gap metabolic acidosis develops.

Distal RTA should be considered in all patients with a non-anion gap metabolic acidosis and hypokalemia who have an inability to lower the urine pH maximally. A urine pH above 5.5 in the setting of systemic acidosis is suggestive of distal RTA, and a UAG value greater than zero is confirmatory. Depending on the duration of the distal RTA, the metabolic acidosis can be either mild or very severe, with a serum bicarbonate concentration as low as 10 mmol/L. Urinary potassium losses lead to the

Factors Differentiating Type 1, Type 2 and Type 4 RTA			
	Type 1 RTA	Type 2 RTA	Type 4 RTA
Serum K ⁺	Low	Low	High
Renal function	Normal or near normal	Normal or near normal	Stage 3, 4, or 5 chronic kidney disease
Urine pH during acidosis	High	Low	Low or high
Serum HCO ₃ ⁻ (mmol/l)	10–20	16–18	16–22
Urine pCO ₂ (mmHg)	< 40	< 40	> 70
Urine citrate	Low	High	Low
Fanconi syndrome	No	May be present	No

Figure 12.6 Factors differentiating types 1, 2, and 4 renal tubular acidosis (RTA).

development of hypokalemia. Severe hypokalemia (<2.5 mmol/l) may result in musculoskeletal weakness and nephrogenic diabetes insipidus. The latter occurs because hypokalemia decreases AQP2 expression in the collecting duct, thereby minimizing the ability to concentrate urine. An abdominal ultrasound scan may reveal nephrocalcinosis.

In patients with minimal disturbances in blood pH and plasma HCO₃⁻ concentration, a test of urinary acidification is required. Traditionally, such a test involved oral NH₄Cl administration to induce metabolic acidosis with assessment of the renal response by serial measurement of urine pH. Many patients poorly tolerate NH₄Cl ingestion because of gastric irritation, nausea, and vomiting. An alternative way to test the capacity for distal acidification is to administer furosemide and the mineralocorticoid fludrocortisone simultaneously.¹³ The combination of both increased distal Na⁺ delivery and mineralocorticoid effect will stimulate distal H⁺ secretion by both an increase in the luminal electronegativity and a direct stimulatory on H⁺ secretion. Normal subjects will lower urine pH to values below 5.5 with either maneuver.

Correction of the metabolic acidosis in distal RTA can be achieved by administration of alkali in an amount only slightly greater than daily acid production (usually 1 to 2 mmol/kg per day). In patients with severe K⁺ deficits, correction of the acidosis with HCO₃⁻, particularly if it is done with sodium alkali salts such as sodium bicarbonate, can lower serum potassium concentration to dangerous levels. In this setting, potassium replacement should begin before the acidosis is corrected. In general, a combination of sodium alkali and potassium alkali is required for long-term treatment of distal RTA. For the patient with recurrent renal stone disease due to distal RTA, treatment of the acidosis increases urinary citrate excretion, which slows the rate of further stone formation and may even lead to stone dissolution.

Hyperkalemic Distal Renal Tubular Acidosis (Type 4)

Type 4 RTA is characterized by distal nephron dysfunction, resulting in impaired renal excretion of both H⁺ and K⁺ and causing a hyperchloremic normal gap acidosis and hyperkalemia.¹⁴ The syndrome occurs most commonly with mild to moderate impairment in renal function; however, the magnitude of hyperkalemia and acidosis are disproportionately severe for the

observed glomerular filtration rate (GFR). Whereas hypokalemic distal (type 1) RTA is also a disorder of distal nephron acidification, type 4 RTA is distinguished from type 1 RTA on the basis of several important characteristics (Fig. 12.6). Type 4 RTA is also a much more common form of RTA, particularly in adults.

Type 4 RTA results from either a deficiency in circulating aldosterone or abnormal cortical collecting duct function, or it can be related to hyperkalemia. In either case, a defect in distal H⁺ secretion develops. Impaired Na⁺ reabsorption by the principal cell leads to a decrease in the luminal electronegativity of the cortical collecting duct, which impairs distal acidification as a result of the decrease in driving force for H⁺ secretion into the tubular lumen. The H⁺ secretion is further impaired in this segment as well as in the medullary collecting duct as a result of either the loss of the direct stimulatory effect of aldosterone on H⁺ secretion or an abnormality in the H⁺ secreting cell.

A consequence of the decrease in luminal electronegativity in the cortical collecting duct is impaired renal K⁺ excretion. In addition, a primary abnormality in the cortical collecting duct transport can also impair K⁺ secretion. The development of hyperkalemia adds to the defect in distal acidification by decreasing the amount of ammonia available to act as a urinary buffer. Some studies suggest that hyperkalemia itself, through its effects on ammonia metabolism, is the primary mechanism by which the metabolic acidosis develops in type 4 RTA.

The etiology of type 4 RTA includes those conditions associated with decreased circulating levels of aldosterone and conditions associated with impaired function of the cortical collecting duct. The most common disease associated with type 4 RTA in adults is diabetes mellitus. In these patients, primary NaCl retention leads to volume expansion and suppression and atrophy of the renin-secreting juxtaglomerular apparatus. Several commonly used drugs, such as nonsteroidal anti-inflammatory agents (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and high doses of heparin, as used for systemic anticoagulation, can lead to decreased mineralocorticoid synthesis. Impaired function of the cortical collecting duct can be a feature of structural damage to the kidney, as in interstitial renal diseases such as sickle cell nephropathy, urinary tract obstruction, and lupus; it may also result from use of drugs such as amiloride, triamterene, and spironolactone.¹⁵

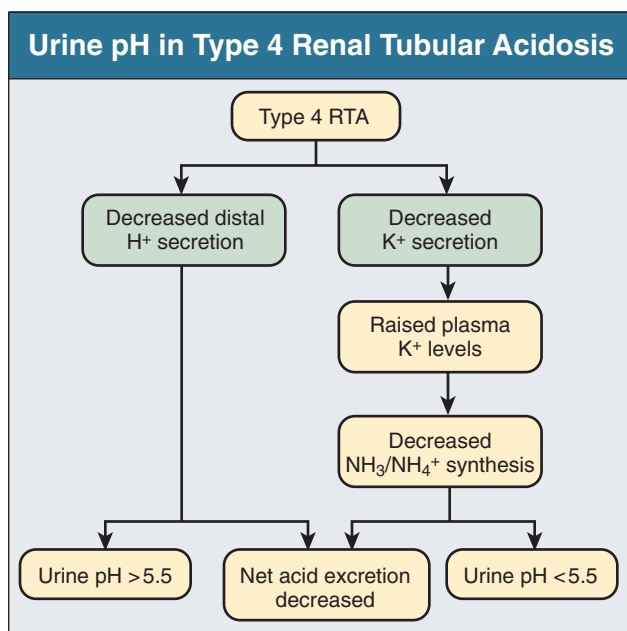

Figure 12.7 Urine pH in type 4 renal tubular acidosis (RTA). Net acid excretion is always decreased; however, the urine pH can be variable. In structural disease of the kidney, the predominant defect is usually decreased distal H^+ secretion, and the urine pH is above 5.5. In disorders associated with decreased mineralocorticoid activity, urine pH is usually below 5.5.

Type 4 RTA should be suspected in a patient with a normal gap metabolic acidosis associated with hyperkalemia. The typical patient is in the fifth to seventh decade of life with a long-standing history of diabetes mellitus with a moderate reduction in the GFR. The plasma HCO_3^- concentration is usually in the range of 18 to 22 mmol/l and the serum K^+ concentration between 5.5 and 6.5 mmol/l. Most patients are asymptomatic; however, the hyperkalemia may occasionally be severe enough to cause muscle weakness or cardiac arrhythmias. The UAG value is slightly positive, indicating minimal ammonia excretion in the urine. Patients in whom the disorder is caused by a defect in mineralocorticoid activity typically have a urine pH below 5.5, reflecting a more severe defect in ammonia availability than in H^+ secretion (Fig. 12.7). In patients with structural damage to the collecting duct, the urine pH may be alkaline, reflecting both impaired H^+ secretion and decreased urinary ammonia excretion.

Treatment of type 4 RTA is directed at treatment of both the hyperkalemia and the metabolic acidosis. In many instances, lowering of the serum K^+ concentration will simultaneously correct the acidosis.¹⁶ Correction of the hyperkalemia allows renal ammonia production to increase, thereby increasing the buffer supply for distal acidification. The first consideration in the treatment of patients is to discontinue any nonessential medication that might interfere in either the synthesis or activity of aldosterone or the ability of the kidneys to excrete potassium (Fig. 12.8). ACE inhibitors and angiotensin receptor blockers (ARBs) should usually be continued because of the beneficial effects on cardiovascular disease and their renoprotective benefits in patients with chronic kidney disease (CKD). In patients with aldosterone deficiency who are neither hypertensive nor fluid overloaded, administration of a synthetic mineralocorticoid such as fludrocortisone (0.1 mg/day) can be effective. In patients with hypertension or volume overload, particularly in association with CKD, administration of either a thiazide or a loop diuretic

is frequently effective. Loop diuretics are required in patients with an estimated GFR below 30 ml/min. Loop and thiazide diuretics increase distal Na^+ delivery and, as a result, stimulate K^+ and H^+ secretion in the collecting duct. Alkali therapy (e.g., NaHCO_3) can also be used to treat the acidosis and hyperkalemia, but one must closely monitor the patient to avoid volume overload and worsening hypertension.

Renal Tubular Acidosis in Chronic Kidney Disease

Metabolic acidosis in advanced CKD is caused by failure of the tubular acidification process to excrete the normal daily acid load. As functional renal mass is reduced by disease, there is an adaptive increase in ammonia production and H^+ secretion by the remaining nephrons. Despite increased production of ammonia from each remaining nephron, overall production may be decreased secondary to the decrease in total renal mass. In addition, there is less delivery of ammonia to the medullary interstitium secondary to a disrupted medullary anatomy.¹⁷ The ability to lower the urinary pH remains intact, reflecting the fact that the impairment in distal nephron H^+ secretion is less than that in ammonia secretion. Quantitatively, however, the total amount of H^+ secretion is small, and the acidic urine pH is the consequence of very little buffer in the urine. The lack of ammonia in the urine is reflected by a positive value for the UAG. Differentiation of RTA from type 4 RTA can be difficult as it is based on the clinician's determination of whether the severity of metabolic acidosis is out of proportion to the degree of renal dysfunction.

Patients with CKD may develop a hyperchloremic normal gap metabolic acidosis associated with normokalemia or mild hyperkalemia as GFR decreases to less than 30 ml/min. With more advanced CKD (GFR <15 ml/min), the acidosis may change to an anion gap metabolic acidosis, reflecting a progressive inability to excrete phosphate, sulfate, and various organic

acids. At this stage, the acidosis is commonly referred to as uremic acidosis.

Correction of the metabolic acidosis in patients with CKD is achieved by treatment with NaHCO_3 , 0.5 to 1.5 mmol/kg per day, beginning when the HCO_3^- level is less than 22 mmol/L. In some cases, non-sodium citrate formulations can be used. Loop diuretics are often used in conjunction with alkali therapy to prevent volume overload. If the acidosis becomes refractory to medical therapy, dialysis needs to be initiated. Recent evidence suggests that metabolic acidosis in the setting of CKD needs to be aggressively treated as chronic acidosis is associated with metabolic bone disease and may lead to an accelerated catabolic state in patients with chronic kidney disease.^{18,19}

Extrarenal Origin

Diarrhea

Intestinal secretions from sites distal to the stomach are rich in HCO_3^- . Accelerated loss of this HCO_3^- -rich solution can result in metabolic acidosis. The resultant volume loss signals the kidney to increase NaCl reabsorption; this combined with the intestinal NaHCO_3 losses generates a normal anion gap metabolic acidosis. The renal response is to increase net acid excretion by increasing urinary excretion of ammonia.²⁰ Hypokalemia, as a result of gastrointestinal losses, and the low serum pH both stimulate the synthesis of ammonia in the proximal tubule. The increase in availability of ammonia to act as a urinary buffer allows a maximal increase in H^+ secretion by the distal nephron.

The increase in urinary ammonia excretion associated with an extrarenal normal anion gap acidosis results in a negative UAG value. Urine pH can be misleading and in chronic diarrhea may be above 6.0 because of substantial increases in renal ammonia metabolism that result in increased urine pH from the buffering ability of the ammonia. Although the clinical history should distinguish between these two possibilities, in a patient with surreptitious laxative abuse, this may not be helpful because diarrhea may not be reported. Colonoscopy may be required to demonstrate characteristic findings of laxative abuse (such as melanosis coli), if this diagnosis is being considered.

Treatment of diarrhea-associated metabolic acidosis is based on treatment of the underlying diarrhea. If this is not possible, alkali treatment, possibly including potassium alkali to treat hypokalemia and metabolic acidosis simultaneously, is indicated.

Ileal Conduits

Surgical diversion of the ureter into an ileal pouch is used in the treatment of neurogenic bladder or after cystectomy. The procedure may rarely be associated with the development of a hyperchloremic normal anion gap metabolic acidosis. Acidosis in part is due to reabsorption of urinary NH_4Cl by the intestine. The ammonia is transported through the portal circulation to the liver or is metabolized to urea to prevent hyperammonemic encephalopathy. This metabolic process consumes equimolar amounts of bicarbonate and therefore can result in the development of metabolic acidosis. Metabolic acidosis may also develop because urinary Cl^- can be exchanged for HCO_3^- through activation of a Cl^- - HCO_3^- exchanger on the intestinal lumen. In some patients, a renal defect in acidification can develop and exacerbate the degree of acidosis. Such a defect may result from tubular damage caused by pyelonephritis or high colonic pressures, secondarily causing urinary obstruction.

The severity of acidosis relates to the length of time the urine is in contact with the bowel and the total surface area of bowel

exposed to urine. In patients with a ureterosigmoid anastomosis, these factors are increased and the acidosis tends to be more common and more severe than in those patients with an ileal conduit. The ileal conduit was designed to minimize the time and area of contact between urine and intestinal surface. Patients with surgical diversion of the ureter who develop metabolic acidosis should be examined for an ileal loop obstruction because this would lead to an increase in contact time between the urine and the intestinal surface.

ANION GAP METABOLIC ACIDOSIS

Lactic Acidosis

Lactic acid is the end product in the anaerobic metabolism of glucose and is generated by the reversible reduction of pyruvic acid by lactic acid dehydrogenase and NADH (reduced nicotinamide adenine dinucleotide), as shown in the following formula:

Under normal conditions, the reaction is shifted toward the right, and the normal lactate to pyruvate ratio is approximately 10:1. The reactants in this pathway are interrelated as shown in the following equation:

$$\text{lactate} = K[(\text{pyruvate})(\text{NADH})(\text{H}^+)]/(\text{NAD}^+)$$

where K is the equilibrium constant.

On the basis of this relationship, it is evident that lactate can increase for three reasons.²¹ First, lactate can increase as a consequence of increased pyruvate production alone. In this situation, the normal 10:1 lactate to pyruvate ratio will be maintained. An isolated increase in pyruvate production can be seen in the setting of intravenous glucose infusions, intravenous administration of epinephrine, and respiratory alkalosis. Lactate levels in these conditions are minimally elevated, rarely exceeding 5 mmol/L. Second, lactate can increase as a result of an increased NADH/NAD^+ ratio. Under these conditions, the lactate to pyruvate ratio can increase to very high values. Finally, lactate can increase when there is a combination of increased pyruvate production with an increased NADH/NAD^+ ratio. This is common in severe lactic acidosis.

Lactic acidosis occurs whenever there is an imbalance between the production and use of lactic acid. The net result is an accumulation of serum lactate and the development of metabolic acidosis. The accumulation of the non-chloride anion lactate accounts for the increase in anion gap. Severe exercise and grand mal seizures are examples of when lactic acidosis can develop as a result of increased production. The short-lived nature of the acidosis in these conditions suggests that a concomitant defect in lactic acid use is present in most conditions of sustained and severe lactic acidosis.

A partial list of the disorders associated with the development of lactic acidosis is given in Figure 12.9. Type A lactic acidosis is characterized by underperfusion of tissue or acute hypoxia, such as hypotension, sepsis, acute tissue hypoperfusion, cardiopulmonary failure, severe anemia, hemorrhage, and carbon monoxide poisoning. Type B lactic acidosis occurs in the absence of overt hypoperfusion or hypoxia, such as with congenital defects in glucose or lactate metabolism, diabetes mellitus, liver disease, effects of drugs and toxins, and neoplastic diseases.²²⁻²⁷ In clinical practice, many patients will often exhibit features of type A and type B lactic acidosis simultaneously.

Causes of Lactic Acidosis	
Type A (tissue underperfusion or hypoxia)	
	Cardiogenic shock
	Septic shock
	Hemorrhagic shock
	Acute hypoxia
	Carbon monoxide poisoning
	Anemia
Type B (absence of hypotension and hypoxia)	
	Hereditary enzyme deficiency (glucose 6-phosphatase)
	Drugs or toxins
	Phenformin, metformin
	Cyanide
	Salicylate, ethylene glycol, methanol
	Propylene glycol ²⁵
	Linezolid ²²
	Propofol ²⁴
	Nucleoside reverse transcriptase inhibitors: stavudine, didanosine ²³
	Clenbuterol ²⁶
	Isoniazid
	Systemic disease
	Liver failure
	Malignancy

Figure 12.9 Causes of lactic acidosis.

Therapy is aimed at correction of the underlying disorder. Restoration of tissue perfusion and oxygenation is attempted if they are compromised. The role of alkali in the treatment of lactic acidosis is controversial; some experimental models and clinical observations suggest that administration of HCO_3^- may depress cardiac function and exacerbate the acidemia. In addition, such therapy may be complicated by volume overload, hypernatremia, and rebound alkalosis after the acidosis has resolved. In general, HCO_3^- should be given when the systemic pH decreases to below 7.1, as hemodynamic instability becomes much more likely with severe acidemia. In such cases, alkali therapy should be directed at increasing the pH above 7.1; attempts to normalize the pH or $[\text{HCO}_3^-]$ should be avoided. Acute hemodialysis is rarely beneficial for lactic acidosis induced by tissue hypoperfusion. The hemodynamic instability that can occur with hemodialysis in these critically ill patients may worsen the underlying difficulty in tissue oxygenation.

Diabetic Ketoacidosis

Diabetic ketoacidosis results from the accumulation of acetoacetic acid and β -hydroxybutyric acid. The development of ketoacidosis is the result of insulin deficiency and a relative or absolute increase in glucagon.²⁸ These hormonal changes lead to increased fatty acid mobilization from adipose tissue and alter the oxidative machinery of the liver such that delivered fatty acids are primarily metabolized into keto acids. In addition, peripheral glucose use is impaired, and the gluconeogenic pathway in the liver is maximally stimulated. The resultant hyperglycemia causes an osmotic diuresis and volume depletion.

Ketoacidosis results when the rate of hepatic keto acid generation exceeds renal excretion, causing increased blood keto acid concentrations. The H^+ accumulation in the extracellular fluid decreases HCO_3^- concentration, whereas the keto acid anion concentration increases. An anion gap metabolic acidosis is the more common finding in diabetic ketoacidosis, but a normal gap metabolic acidosis can also be seen. In early stages

of ketoacidosis, when the extracellular volume is nearly normal, keto acid anions that are produced are rapidly excreted by the kidney as Na^+ and K^+ salts. Excretion of these salts is equivalent to the loss of potential HCO_3^- . This loss of potential HCO_3^- in the urine at the same time that the kidney is retaining NaCl results in a normal gap metabolic acidosis. As volume depletion develops, renal keto acid excretion cannot match production rates, and keto acid anions are retained within the body, thus increasing the anion gap.

During treatment, the anion gap metabolic acidosis transforms once again into a normal gap acidosis. Treatment leads to a termination in keto acid production. As the extracellular fluid volume is restored, there is increased renal excretion of the Na^+ salts of the keto acid anions. The loss of this potential HCO_3^- combined with the retention of administered NaCl accounts for the redevelopment of the hyperchloremic normal gap acidosis. In addition, K^+ and Na^+ administered in solutions containing NaCl and KCl enter cells in exchange for H^+ . The net effect is infusion of HCl into the extracellular fluid. The reversal of the hyperchloremic acidosis takes several days as the HCO_3^- deficit is corrected by the kidney.

Diabetic ketoacidosis can result in a severe metabolic acidosis with serum bicarbonate levels below 5 mmol/L. This diagnosis should be considered in patients with simultaneous metabolic acidosis and hyperglycemia. Diagnosis is confirmed by demonstration of retained keto acids with nitroprusside tablets or reagent strips. However, these tests detect only acetone and acetoacetate and not β -hydroxybutyrate. In the setting of lactic acidosis or alcoholic ketoacidosis, acetoacetate may be converted to β -hydroxybutyrate to an extent that depends on the NADH/NAD^+ ratio. With treatment of the diabetic ketoacidosis, acetoacetate is generated as the NADH/NAD^+ ratio falls, and the nitroprusside test result may suddenly become strongly positive.

The limitations of the nitroprusside test can be prevented by direct measurement of β -hydroxybutyrate. With uncontrolled diabetes, a serum β -hydroxybutyrate level above 3.0 and above 3.8 mmol/L in children and adults, respectively, confirms diabetic ketoacidosis.²⁹ Compared with urinary ketone measurements, capillary blood levels of β -hydroxybutyrate better correlate with both the degree of acidosis and the response to therapy.³⁰

Treatment consists of insulin and intravenous fluids to correct volume depletion. Deficiencies in K^+ , Mg^{2+} , and phosphate are common; therefore, these electrolytes are typically added to intravenous solutions. However, diabetic ketoacidosis typically presents with hyperkalemia due to the insulin deficiency. Potassium should be administered only as hypokalemia develops, usually during insulin treatment of diabetic ketoacidosis. If there is significant hypokalemia at presentation, potassium supplementation may be needed before insulin administration to avoid life-threatening worsening of hypokalemia. Alkali therapy is generally not required because administration of insulin leads to the metabolic conversion of keto acid anions to HCO_3^- and allows partial correction of the acidosis. However, HCO_3^- therapy may be indicated in those patients who present with severe acidemia ($\text{pH} < 7.1$).³¹

D-Lactic Acidosis

D-Lactic acidosis is a unique form of metabolic acidosis that can occur in the setting of small bowel resections or in patients with a jejunoileal bypass. Such short bowel syndromes create a situation in which carbohydrates that are normally extensively

reabsorbed in the small intestine are delivered in large amounts to the colon. In the presence of colonic bacterial overgrowth, these substrates are metabolized into D-lactate and absorbed into the systemic circulation. Accumulation of D-lactate produces an anion gap metabolic acidosis in which the serum lactate concentration is normal because the standard test for lactate is specific for L-lactate. These patients typically present after ingestion of a large carbohydrate meal with neurologic abnormalities consisting of confusion, slurred speech, and ataxia. Ingestion of low-carbohydrate meals and antimicrobial agents to decrease the degree of bacterial overgrowth are the principal treatments.

Starvation Ketosis

Abstinence from food can lead to a mild anion gap metabolic acidosis secondary to increased production of keto acids. The pathogenesis of this disorder is similar to that of diabetic ketoacidosis in that starvation leads to relative insulin deficiency and glucagon excess. As a result, there is increased mobilization of fatty acids while the liver is set to oxidize fatty acids to keto acids. With prolonged starvation, the blood keto acid level can reach 5 to 6 mmol/L. The serum $[\text{HCO}_3^-]$ is rarely less than 18 mmol/L. More fulminant ketoacidosis is aborted by the fact that ketone bodies stimulate the pancreatic islets to release insulin and lipolysis is held in check. This break in the ketogenic process is notably absent in those with insulin-dependent diabetes. There is no specific therapy indicated in this disorder.

Alcoholic Ketoacidosis

Ketoacidosis develops in patients with a history of chronic ethanol abuse, decreased food intake, and often a history of nausea and vomiting. As with starvation ketosis, a decrease in the insulin to glucagon ratio leads to accelerated fatty acid mobilization and alters the enzymatic machinery of the liver to favor keto acid production. However, there are features unique to this disorder that differentiate it from simple starvation ketosis. First, the alcohol withdrawal combined with volume depletion and starvation markedly increases the levels of circulating catecholamines. As a result, the peripheral mobilization of fatty acids is much greater than that typically found with starvation alone. This sometimes massive mobilization of fatty acids can lead to marked keto acid production and severe metabolic acidosis. Second, the metabolism of ethanol leads to accumulation of NADH. The increase in the NADH/NAD⁺ ratio is reflected by a higher β -hydroxybutyrate to acetoacetate ratio. As mentioned previously, the nitroprusside reaction may be diminished by this redox shift despite the presence of severe ketoacidosis. Treatment of this disorder is focused on glucose administration, which leads to the rapid resolution of the acidosis because stimulation of insulin release leads to diminished fatty acid mobilization from adipose tissue as well as decreased hepatic output of keto acids.

Ethylene Glycol and Methanol Intoxications

Ethylene glycol and methanol intoxications are characteristically associated with the development of a severe anion gap metabolic acidosis. Metabolism of ethylene glycol by alcohol dehydrogenase generates various acids, including glycolic, oxalic, and formic acids. Ethylene glycol is present in antifreeze and solvents and is ingested by accident or as a suicide attempt. The initial effects of intoxication are neurologic and begin with drunkenness but can quickly progress to seizures and coma. If left untreated,

Ethylene Glycol and Methanol Poisoning

Time course of clinical symptoms and signs after ingestion
Ethylene glycol
0–12 hours: inebriation progressing to coma
12–24 hours: tachypnea, noncardiogenic pulmonary edema
24–36 hours: flank pain, renal failure, urinary calcium oxalate crystals
Methanol
0–12 hours: inebriation followed by asymptomatic period
24–36 hours: pancreatitis, retinal edema progressing to blindness, seizures
>48 hours: putamen and white matter hemorrhage leading to Parkinson's disease–like state
Increased anion gap metabolic acidosis
Increased osmolar gap
Treatment
Supportive care
Fomepizole (4-methylpyrazole) is agent of choice (competitor of alcohol dehydrogenase): 15 mg/kg IV loading dose, then 10 mg/kg every 12 hours for 48 hours; after 48 hours, increase dose to 15 mg/kg every 12 hours; increase frequency of dosing to 4 hours during hemodialysis
Intravenous ethanol (5% or 10% solution) if fomepizole unavailable: loading dose of 0.6 g/kg followed by hourly maintenance dose of 66 mg/kg; increase maintenance dose when there is a history of chronic alcohol use and during hemodialysis
Hemodialysis to accelerate removal of parent compound and metabolites
Bicarbonate therapy to treat acidosis

Figure 12.10 Ethylene glycol and methanol poisoning.

cardiopulmonary symptoms such as tachypnea, noncardiogenic pulmonary edema, and cardiovascular collapse may appear. Twenty-four to 48 hours after ingestion, patients may develop flank pain and acute kidney injury often accompanied by abundant calcium oxalate crystals in the urine (Fig. 12.10). A fatal dose is approximately 100 mL.

Methanol is also metabolized by alcohol dehydrogenase and forms formaldehyde, which is then converted to formic acid. Methanol is found in a variety of commercial preparations, such as shellac, varnish, and de-icing solutions, and is also known as wood alcohol. Like ethylene glycol, methanol can be ingested either by accident or as a suicide attempt. Clinically, methanol ingestion is associated with an acute inebriation followed by an asymptomatic period lasting 24 to 36 hours. Abdominal pain caused by pancreatitis, seizures, blindness, and coma may develop. The blindness is due to direct toxicity of formic acid on the retina. Methanol intoxication is also associated with hemorrhage in the white matter and putamen, which can lead to the delayed onset of a Parkinson's disease–like syndrome (see Fig. 12.10). The lethal dose is between 60 and 250 mL. Lactic acidosis is also a feature of methanol and ethylene glycol poisoning and contributes to the elevated anion gap.

Together with an elevated anion gap, an osmolar gap is an important clue to the diagnosis of ethylene glycol and methanol poisoning. The osmolar gap is the difference between the measured and calculated osmolality. The formula for the calculated osmolality is as follows:

$$\text{calculated osmolality} = \frac{2 \times \text{Na}^+ + \text{BUN}}{2.8} + \frac{\text{glucose}}{18} + \frac{\text{EtOH}}{4.6}$$

where the blood urea nitrogen (BUN), glucose, and ethanol concentrations are in milligrams per deciliter. Inclusion of the ethanol concentration in this calculation is important as many patients who ingest either ethylene glycol or methanol do so while inebriated from ethanol ingestion. The normal value for the osmolar gap is less than 10 mOsm/kg. Each 100 mg/dl (161 mmol/l) of ethylene glycol will increase the osmolar gap by 16 mOsm/kg; methanol contributes 32 mOsm/kg for each 100 mg/dl (312 mmol/l).

In addition to supportive measures, ethylene glycol and methanol poisoning are treated with fomepizole (4-methylpyrazole), which inhibits alcohol dehydrogenase and prevents formation of toxic metabolites (see Fig. 12.10).³² If fomepizole is unavailable, intravenous ethanol can be used to prevent the formation of toxic metabolites. Ethanol has more than a 10-fold greater affinity for alcohol dehydrogenase than that of other alcohols. Ethanol has its greatest efficacy when levels of 100 to 200 mg/dl are obtained. In addition to both fomepizole and ethanol therapy, hemodialysis should be employed to remove both the parent compound and its metabolites. Finally, correction of the acidosis is accomplished with use of an HCO_3^- -containing dialysate or by intravenous infusion of NaHCO_3 .

Salicylate

Aspirin (acetylsalicylic acid) is associated with a large number of accidental or intentional poisonings. At toxic concentrations, salicylate uncouples oxidative phosphorylation and, as a result, leads to increased lactic acid production. In children, keto acid production may also be increased. The accumulation of lactic, salicylic, keto, and other organic acids leads to the development of an anion gap metabolic acidosis. At the same time, salicylate has a direct stimulatory effect on the respiratory center. Increased ventilation lowers the Pco_2 , contributing to the development of a respiratory alkalosis. Children primarily manifest an anion gap metabolic acidosis with toxic salicylate levels; a respiratory alkalosis is most evident in adults.

In addition to conservative management, the initial goals of therapy are to correct systemic acidemia and to increase the urine pH. By increasing systemic pH, the ionized fraction of salicylic acid will increase, and as a result, there will be less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH favors increased urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations above 80 mg/dl or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate drug elimination.

Pyroglutamic Acidosis

Pyroglutamic acid, also known as 5-oxoproline, is an intermediate in glutathione metabolism. An anion gap acidosis due to pyroglutamic acid has been rarely described in critically ill patients receiving therapeutic doses of acetaminophen (Fig. 12.11).^{33,34} Affected patients present with severe anion gap metabolic acidosis accompanied by alterations in mental status ranging from confusion to coma. High concentrations of pyroglutamic acid are found in the blood and urine. In this setting, glutathione levels are reduced because of the oxidative stress associated with critical illness and by the metabolism of acetaminophen. The reduction in glutathione secondarily leads to increased production of pyroglutamic acid. The diagnosis of pyroglutamic

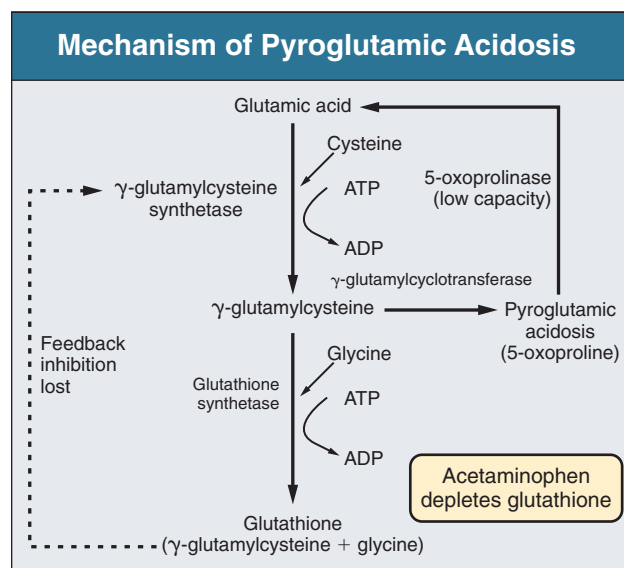

Figure 12.11 Mechanism of pyroglutamic acidosis. Glutathione is formed from γ -glutamylcysteine and glycine in the presence of glutathione synthetase. Glutathione normally regulates the activity of γ -glutamylcystine synthetase through feedback inhibition. Depletion of glutathione results in increased formation of γ -glutamylcysteine, which in turn is metabolized to pyroglutamic acid (5-oxoproline) and cystine through γ -glutamylcyclotransferase. Pyroglutamic acid accumulates because the enzyme responsible for its metabolism (5-oxoproline dehydrogenase) is low capacity. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

acidosis should be considered in patients with unexplained anion gap metabolic acidosis and recent acetaminophen ingestion.

ALKALI TREATMENT OF METABOLIC ACIDOSIS

Treatment of metabolic acidosis usually involves either sodium bicarbonate or citrate (Fig. 12.12).³¹ Sodium bicarbonate can be taken orally as tablets or powder or given intravenously as a hypertonic sodium bicarbonate bolus or an isotonic sodium bicarbonate infusion, which can be created by adding three ampules ("amps") of sodium bicarbonate (50 mmol/amp) to a liter of 5% dextrose in water (D_5W) solution. This solution is useful if treatment requires both volume expansion and alkali administration.

Citrate may be taken orally as a liquid, as sodium citrate, potassium citrate, or citric acid and as a combination of these. Many patients find citrate-containing solutions more palatable than oral sodium bicarbonate as a source of oral alkali therapy. Oral citrate therapy should not be combined with medications that include aluminum. Citrate, which has a -3 charge under normal conditions, can complex with aluminum (Al^{3+}) in the intestinal tract, resulting in an uncharged moiety that is rapidly absorbed across the intestinal tract and then can dissociate to release free aluminum. This can increase the rate of aluminum absorption dramatically and in some cases, particularly in patients with severe CKD, has resulted in acute aluminum encephalopathy.

The dose of alkali therapy that is administered is based on both the total body bicarbonate deficit and the desired rapidity of treatment. Under normal circumstances, the volume of distribution (V_D) for bicarbonate is approximately 0.5 l/kg total body weight. Thus, the bicarbonate deficit, in millimoles, can be estimated from the following formula:

Alkali Treatment Options			
	Route	Usual Dose per Unit	Comments
Sodium bicarbonate tablet	PO	650 mg = 8 mmol	May cause gastric gas
Sodium bicarbonate	IV	50 mmol in 50 ml	Hypertonic, may cause hyponatremia
D ₅ W with NaHCO ₃	IV	150 mmol/l	Useful for simultaneous intravascular volume expansion and alkali administration
Sodium citrate/citric acid (liquid)	PO	1 mmol of Na ⁺ and citrate per milliliter	1 mmol citrate equivalent to 1 mmol HCO ₃ ⁻ . Avoid concomitant aluminum-containing medications such as antacids and sucralfate.
Potassium citrate (tablet)	PO	5 and 10 mmol per tablet	Useful for simultaneous K ⁺ and alkali therapy
Citric acid/potassium citrate/sodium citrate (liquid)	PO	1 mmol of Na ⁺ and K ⁺ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications
Potassium citrate (liquid)	PO	2 mmol of K ⁺ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications

Figure 12.12 Alkali treatment options.

$$\text{bicarbonate deficit} = (0.5 \times \text{LBW}_{\text{kg}}) \times (24 - \text{HCO}_3^-)$$

where LBW_{kg} is the lean body weight in kilograms and 24 is the desired resultant bicarbonate concentration.

Several caveats regarding this equation should be understood. First, edema fluid contributes to the volume of distribution of bicarbonate. Accordingly, an estimation of the amount of edema fluid should be included in this calculation. Second, the volume of distribution for bicarbonate increases as the severity of the metabolic acidosis worsens. When the serum bicarbonate concentration is 5 mmol/l or less, the volume of distribution may increase to 1 l/kg or more.

When acute treatment is desired, 50% of the bicarbonate deficit should be replaced during the first 24 hours. If hypertonic sodium bicarbonate is administered, the increase in serum bicarbonate concentration will be mirrored by an increase in serum sodium concentration. After the initial 24 hours of therapy, the response to therapy and the patient's current clinical condition are re-evaluated before future therapy is decided. Acute hemodialysis solely for the treatment of metabolic acidosis other than that associated with renal failure is rarely beneficial.

Metabolic Alkalosis

F. John Gennari

DEFINITION

Metabolic alkalosis is caused by retention of excess alkali and is manifested by an increase in venous [total CO_2] to greater than 30 mmol/l or in arterial [HCO_3^-] to greater than 28 mmol/l. The increase in pH that results from retained HCO_3^- induces hypoventilation, producing a secondary increase in arterial Pco_2 . Thus, the disorder is characterized by coexisting elevations in serum [HCO_3^-], arterial pH, and Pco_2 . Because the kidney normally responds to an increase in [HCO_3^-] by rapidly excreting the excess alkali, sustained metabolic alkalosis occurs only when some additional factor disrupts renal regulation of body alkali stores.

RENAL BICARBONATE TRANSPORT MECHANISMS

To examine the ways in which alkali balance is disrupted by metabolic alkalosis, a brief review of normal H^+ and HCO_3^- transport in the kidney is necessary. Bicarbonate ions are freely filtered across the glomerulus and must be completely recaptured from the tubule urine to conserve body alkali stores. In addition, acid excretion must occur to regenerate any HCO_3^- consumed in buffering of endogenously produced acids. Both tasks are accomplished by secretion of H^+ into the renal tubules.¹ Bicarbonate ions are recaptured when secreted H^+ combines with filtered HCO_3^- to produce CO_2 and water, removing HCO_3^- from the urine. At the same time, the secreted H^+ generates new HCO_3^- inside the cell that is then added to the peritubular blood.

Figure 13.1 illustrates the major apical membrane epithelial transporters and channels that participate in HCO_3^- reabsorption. In the proximal tubule and ascending limb of Henle's loop, H^+ is secreted through a Na^+ -linked transporter (the Na^+ - H^+ exchanger NHE3) and also by an H^+ -ATPase. In the collecting duct, NHE3 is not present and H^+ secretion is accomplished primarily by an apical membrane H^+ -ATPase. The activity of this H^+ -ATPase is regulated by aldosterone and by the rate of Na^+ delivery to and reabsorption by the collecting duct. When body K^+ stores are low, an apical membrane H^+ , K^+ -ATPase is activated in the collecting duct, further promoting H^+ secretion driven by K^+ reabsorption.² If excess alkali is ingested, HCO_3^- can re-enter the tubule urine in the collecting duct through an apical membrane Cl^- - HCO_3^- exchanger (pendrin).³ This transporter is activated by alkalemia and requires Cl^- reabsorption in exchange for secreted HCO_3^- . The HCO_3^- secreted into the urine by this transporter can be recaptured again by H^+ secretion in the collecting duct, so that excretion of excess alkali requires both stimulation of the Cl^- - HCO_3^- exchanger and suppression of the normally active collecting duct H^+ -ATPase. As discussed

later, abnormal stimulation of H^+ -secreting transporters or changes in the activity of Na^+ -linked Cl^- transporters in the loop of Henle and early distal tubule (see Fig. 13.1) can disrupt the renal regulation of body alkali stores and produce sustained metabolic alkalosis.

PATHOPHYSIOLOGY OF METABOLIC ALKALOSIS

Metabolic alkalosis can be produced by administration of HCO_3^- (or a HCO_3^- precursor) or by induction of either Cl^- or K^+ depletion. More rarely, sustained metabolic alkalosis is the result of primary abnormalities in the regulation of specific ion transporters in the loop of Henle, distal tubule, or collecting ducts. The most common clinical presentation of metabolic alkalosis is associated with Cl^- depletion. Although the term *contraction alkalosis* is often used as a synonym for Cl^- depletion alkalosis, this phrase is confusing because it implies that volume contraction is responsible for the disorder. The term refers specifically to the increase in serum [HCO_3^-] that follows only one type of extracellular fluid (ECF) volume contraction, that caused by selective Cl^- losses. Moreover, a sustained change in renal HCO_3^- reabsorption and acid excretion must occur for this increase to be maintained, and it remains unclear whether volume contraction is necessary or instrumental in inducing this change in renal function.^{4,5} As is illustrated later, Cl^- and K^+ depletion are closely linked events in causing many forms of sustained metabolic alkalosis, and it is often difficult to determine which ion is the primary culprit. However, experimental depletion of either ion can be shown to induce sustained metabolic alkalosis.⁵⁻⁷

Potassium Depletion

Induction of net K^+ loss by severe restriction of dietary K^+ intake produces a small but significant increase in serum [HCO_3^-].⁶ When dietary Cl^- intake is concomitantly restricted, however, the resultant alkalosis is four times as great, illustrating the complementary roles of Cl^- and K^+ in regulating renal HCO_3^- reabsorption. Depletion of body K^+ stores is probably the most important factor in producing and sustaining the rarer forms of metabolic alkalosis induced by mineralocorticoid excess or apparent mineralocorticoid excess (see later discussion).

Chloride Depletion

Selective Cl^- depletion, induced by vomiting or nasogastric suction, increases serum [HCO_3^-] (Fig. 13.2).⁷ The degree of alkalosis generated is greater when H^+ loss also occurs, as in the example shown in Figure 13.2, but it may occur even when H^+ loss is minimized by administration of a proton pump inhibitor. In either setting, maintenance of the metabolic alkalosis is

Figure 13.1 Key apical membrane ion transporters along the nephron. Bicarbonate ions (HCO_3^-) are recaptured by H^+ secretion throughout the renal tubules. In the proximal tubule and loop of Henle, H^+ secretion is directly linked to Na^+ reabsorption through the Na^+ - H^+ exchanger. In addition, H^+ secretion occurs in these tubule segments through an apical membrane H^+ -ATPase (not shown). In the collecting duct, H^+ secretion is indirectly coupled to Na^+ uptake through a Na^+ channel and parallel H^+ -ATPase. Chloride-linked Na^+ reabsorption in the loop of Henle and early distal tubule affects H^+ secretion by determining Na^+ delivery to the collecting duct. Bicarbonate secretion occurs under conditions of alkalemia through a Cl^- -linked exchanger. Potassium reabsorption in states of K^+ depletion is linked to H^+ secretion through a H^+ , K^+ -ATPase.

dependent on sustaining the depletion of body Cl^- stores. Serum $[\text{HCO}_3^-]$ returns to normal when sufficient Cl^- is given to replenish losses. Chloride-depletion metabolic alkalosis causes concomitant K^+ depletion through renal K^+ losses, but Cl^- administration corrects the alkalosis even if the K^+ deficit is deliberately maintained.⁸ The role of Cl^- depletion, as opposed to ECF volume depletion, and the contribution of K^+ depletion in sustaining this form of metabolic alkalosis remain controversial.^{4,8} Dissection of the contribution of each factor is of little importance in the clinic, however, as treatment is dictated by the particular clinical setting; some patients need NaCl to replenish extracellular volume, and most need KCl to treat K^+ depletion. A less severe Cl^- -dependent metabolic alkalosis, without evident H^+ loss, is generated by the administration of thiazide or loop diuretics.

Interplay of K^+ , Cl^- , and HCO_3^- Transport by the Kidney

When metabolic alkalosis is induced by Cl^- depletion and dietary Cl^- intake is restricted, a characteristic sequence of changes in renal electrolyte excretion occurs.⁷ Sodium and HCO_3^- excretion increase transiently, then decrease rapidly to low levels, and K^+

Figure 13.2 Effect of gastric drainage on plasma $[\text{HCO}_3^-]$ and $[\text{Cl}^-]$ and on the net balance of these two ions in the body in a normal individual ingesting a NaCl -restricted diet. Changes in net acid excretion are also shown. Gastric drainage on three consecutive nights in this subject increased plasma $[\text{HCO}_3^-]$ by 9 mmol/l, a change that persisted after gastric drainage was stopped. Potassium depletion occurs as a result of renal K^+ losses during the period of gastric drainage. These losses are not regained, however, after the drainage is discontinued despite the continued daily ingestion of 70 mmol of K^+ . Net acid excretion decreases transiently during the period of drainage but then returns to control levels despite sustained metabolic alkalosis. Chloride depletion is maintained by the low dietary intake of this ion.

excretion increases. The increase in K^+ excretion is also transient but nonetheless induces significant K^+ depletion (see Fig. 13.2). In the new steady state, urinary K^+ excretion matches intake despite persistent K^+ depletion. As a result, hypokalemia is a cardinal feature of metabolic alkalosis. Potassium depletion stimulates both H^+ secretion (through the H^+ , K^+ -ATPase; see Fig. 13.1) and may also stimulate HCO_3^- reabsorption in the ascending limb of the loop of Henle.⁹ It also stimulates renal NH_4^+ production, facilitating the acid excretion needed to sustain metabolic alkalosis (Fig. 13.3). Although the Cl^- - HCO_3^- exchanger is activated by metabolic alkalosis, continued secretion of aldosterone and collecting duct H^+ secretion appear to recapture all the secreted HCO_3^- and allow continued acid excretion. As a result, acid excretion matches net acid production in the steady state despite systemic alkalemia. When K^+ depletion is unusually severe, renal Cl^- reabsorption is also impaired, possibly by a limitation in Cl^- transport through the Na^+ - K^+ - 2Cl^- cotransporter (see Fig. 13.1), resulting in persistent Cl^- depletion despite intake or administration of this anion.¹⁰

Exogenous Alkali

The kidney responds rapidly to excess alkali by increasing HCO_3^- excretion, and thus metabolic alkalosis can be induced only transiently by alkali administration when renal function is

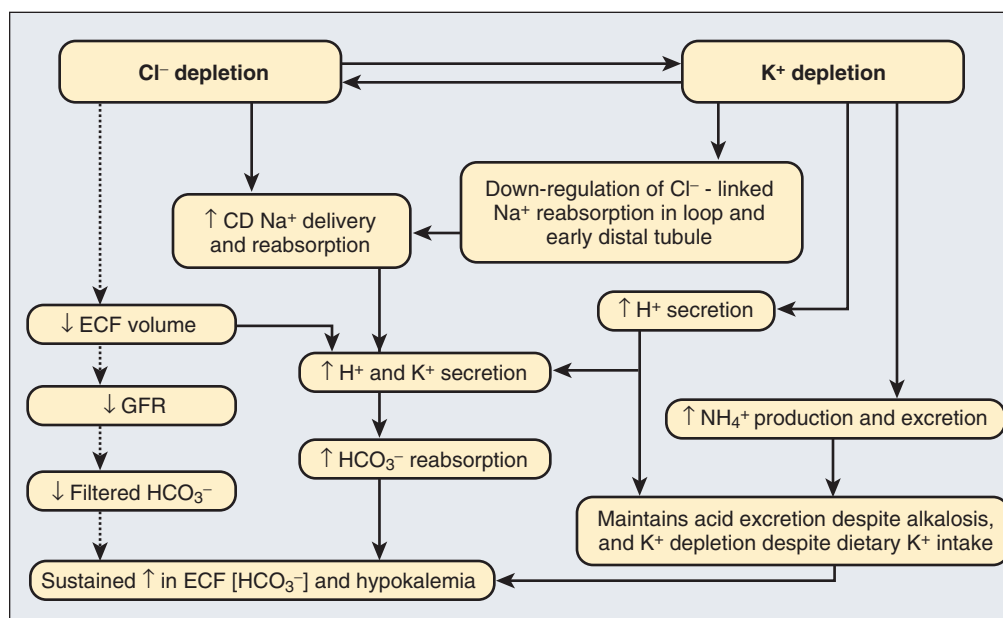

Figure 13.3 Pathophysiology of chloride-responsive metabolic alkalosis. Chloride depletion stimulates H^+ and K^+ secretion in the collecting duct as a result of disproportionate distal Na^+ delivery and reabsorption. The resultant K^+ depletion further stimulates H^+ secretion and promotes ammonium (NH_4^+) production and excretion as well as downregulating Na^+ reabsorption in the loop of Henle. These events all contribute to a sustained increase in serum $[\text{HCO}_3^-]$. Chloride depletion also reduces GFR and therefore HCO_3^- filtration, reducing potential alkali losses. As indicated by the dashed lines, the role of this effect in sustaining metabolic alkalosis remains controversial. CD, collecting duct.

normal. Even when supplemental NaHCO_3 is ingested daily, serum $[\text{HCO}_3^-]$ does not increase unless dietary Cl^- intake is severely restricted.¹¹ If renal HCO_3^- excretion is impaired as a result of kidney failure, alkali administration can cause a sustained metabolic alkalosis independent of Cl^- intake.¹²

Primary Abnormalities in Renal Ion Transport

Acquired or inherited abnormalities in ion transport in the loop and distal tubule can cause metabolic alkalosis (Fig. 13.4). These forms of metabolic alkalosis account for less than 1% of all causes, and by far the most common of these is primary hyperaldosteronism.¹³ In this disorder, persistently high and unregulated aldosterone secretion promotes Na^+ reabsorption and H^+ and K^+ secretion in the collecting duct by stimulating both the epithelial Na^+ channel and H^+ -ATPase (see Figs. 13.1 and 13.4). The resultant K^+ depletion promotes NH_4^+ production and activates H^+ , K^+ -ATPase activity, facilitating acid excretion. Sodium retention leads to hypertension and also ensures continued Na^+ delivery to the collecting duct, sustaining the cycle of increased reabsorption and increased K^+ and H^+ secretion. As a result of all these events, metabolic alkalosis is sustained despite normal Cl^- intake. Not surprisingly, the degree of alkalosis induced by primary hyperaldosteronism is modulated by both Cl^- and K^+ intake. More rarely, metabolic alkalosis is caused by genetic mutations in the regulation and function of specific transporters in the loop of Henle and distal nephron (see the section on etiology, Fig. 13.4, and Chapter 47).

Secondary Response to an Increase in Serum $[\text{HCO}_3^-]$

Regardless of the cause, blood pH increases in metabolic alkalosis and elicits secondary hypoventilation, increasing arterial Pco_2 . The response is a potent one, occurring despite the concomitant

Figure 13.4 Primary derangements in renal ion transport that lead to sustained metabolic alkalosis. The epithelial Na^+ channel in the collecting duct is stimulated abnormally in primary hyperaldosteronism and in three defined genetic abnormalities. One of these causes aldosterone secretion to respond to adrenocorticotrophic hormone rather than to angiotensin II (glucocorticoid-remediable aldosteronism); one blocks downregulation of the channel (Liddle syndrome), and one allows cortisol to act as a mineralocorticoid (11 β -hydroxysteroid dehydrogenase deficiency). Bartter and Gitelman's syndromes are caused by genetic abnormalities that impede the activity of or inactivate Cl^- -linked Na^+ reabsorption in two separate transporters in the nephron.

Figure 13.5 Amelioration of alkalemia by the normal ventilatory response to the increase in serum $[\text{HCO}_3^-]$ in metabolic alkalosis. The red (upper) line in the graph illustrates the relationship between arterial pH and serum $[\text{HCO}_3^-]$ in the absence of adaptive hypoventilation (PCO_2 maintained at 40 mm Hg), and the green (lower) line, the relationship when PCO_2 is increased by the expected level of hypoventilation.

development of hypoxemia. On average, Pco_2 increases by 0.7 mm Hg (0.1 kPa) for each 1 mmol/l increase in serum $[\text{HCO}_3^-]$. Assuming a normal $[\text{HCO}_3^-]$ and Pco_2 of 24 mmol/l and 40 mm Hg, respectively, the predicted Pco_2 for any given serum $[\text{HCO}_3^-]$ in metabolic alkalosis can be calculated as follows:

$$\text{Pco}_2 (\text{mm Hg}) = 40 + 0.7 \times ([\text{HCO}_3^-] (\text{mmol/l}) - 24)$$

Although this formula is helpful in determining whether the ventilatory response to metabolic alkalosis is appropriate, it implies a precision that does not exist in nature. Variations of up to 5 to 7 mm Hg between the observed and calculated Pco_2 may occur in health. Even in severe metabolic alkalosis (serum $[\text{HCO}_3^-] > 50$ mmol/l), the Pco_2 (in mm Hg) virtually always exceeds the value for the serum $[\text{HCO}_3^-]$ (in mmol/l).¹⁴ Figure 13.5 illustrates the ameliorating effect of increasing Pco_2 on pH in metabolic alkalosis. Whereas it mitigates the alkalemia, the increase in Pco_2 also directly stimulates renal HCO_3^- reabsorption, increasing serum $[\text{HCO}_3^-]$ further.¹⁵ This effect is small and unimportant in the clinical setting.

ETIOLOGY

The major causes of metabolic alkalosis are subdivided into three groups based on pathophysiology. The most common causes are induced and sustained by chloride depletion, due to abnormal losses from the gut or the kidney. The second subgroup, much rarer, includes the metabolic alkaloses induced and sustained by excess adrenal corticosteroids, or by collecting duct transport abnormalities that mimic excess mineralocorticoid activity. The third subgroup includes the causes of metabolic alkalosis caused by alkali administration or ingestion. This new classification replaces the traditional separation of causes based on treatment response (chloride-responsive and chloride-resistant) with a more straightforward and inclusive grouping. It also combines logically the causes of metabolic alkalosis that have the same pathophysiology (e.g., Bartter and Gitelman's syndrome and diuretic-induced metabolic alkalosis).

Causes of Chloride-Depletion Metabolic Alkalosis

Chloride loss from the stomach (common)
Vomiting
Nasogastric suction
Diuretic administration (common)
Thiazides
Metolazone
Loop diuretics: furosemide, bumetanide, torsemide, ethacrynic acid
Chloride-depleting diarrheas (rare)
Congenital chloridorrhea
Some villous adenomas of the colon
High-volume ileostomy losses
Impaired chloride-linked sodium transport (rare)
Bartter syndrome
Gitelman's syndrome
Recovery from chronic hypercapnia (rare)
Gastrocystoplasty (rare)
Cystic fibrosis (rare)
Severe potassium deficiency (rare)

Figure 13.6 Causes of chloride-depletion metabolic alkalosis.

Chloride Depletion Metabolic Alkalosis

Figure 13.6 lists the causes of chloride depletion metabolic alkalosis.

Vomiting or Nasogastric Drainage

Loss of chloride from the upper gastrointestinal tract, often accompanied by concomitant H^+ losses, produces a metabolic alkalosis that is sustained until body Cl^- stores are replenished (see Fig. 13.2). With continued emesis or nasogastric suction and without replacement of Cl^- losses, serum $[\text{HCO}_3^-]$ may rise to very high levels (>45 mmol/l).¹⁴

Diuretic Administration

Diuretics that inhibit Cl^- transport proteins in the kidney are the most common cause of metabolic alkalosis (see Fig. 13.6). The thiazides and metolazone inhibit the $\text{Na}^+\text{-Cl}^-$ cotransporter in the early distal tubule, and the loop diuretics inhibit the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter in the ascending limb of the loop of Henle (see Fig. 13.1). These agents all impair Cl^- reabsorption, causing selective Cl^- depletion, and stimulate K^+ excretion by increasing Na^+ delivery to the collecting duct. The alkalosis produced is typically mild (serum $[\text{HCO}_3^-] < 36$ mmol/l), except in patients who continue to ingest excess salt and have extreme renal Na^+ avidity. Hypokalemia due to K^+ depletion is more prominent and is the major management problem.¹⁶

Impairment of Cl^- -Linked Na^+ Transport

Bartter and Gitelman's syndromes are two hereditary disorders manifested by metabolic alkalosis and hypokalemia, but without hypertension (see Chapter 47). Bartter syndrome is caused by several mutations, all of which have the effect of impeding Cl^- -associated Na^+ reabsorption in the ascending limb of the loop of Henle (through the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter; see Fig. 13.4).^{17,18} Patients with this syndrome usually become ill early in life with metabolic alkalosis and volume depletion, features similar to those seen in individuals abusing loop diuretic agents. Gitelman's syndrome is caused by genetic mutations that inactivate the

thiazide-sensitive Na^+ - Cl^- cotransporter in the early distal tubule (see Fig. 13.4), leading to hypokalemia and metabolic alkalosis similar to that caused by thiazide diuretics.¹⁸ Gitelman's syndrome becomes clinically apparent later in life and differs from Bartter syndrome in that hypomagnesemia and hypocalciuria are prominent features.¹⁷

Recovery from Chronic Hypercapnia

The renal response to sustained hypercapnia results in an increase in HCO_3^- reabsorption and a decrease in Cl^- reabsorption (see Chapter 14). As a result, serum $[\text{HCO}_3^-]$ increases and body Cl^- stores are reduced. When Pco_2 is restored to normal, renal excretion of excess HCO_3^- requires repletion of the Cl^- losses incurred during adaptation. If these losses are not replaced, recovery from hypercapnia can result in a persistent metabolic alkalosis.

Congenital Chloridorrhea

This rare form of diarrhea is caused by an inactivating mutation in the “down-regulated in adenoma” (*DRA*) gene, an apical membrane Cl^- - HCO_3^- exchanger in the small intestine.¹⁹ The result is a large-volume diarrhea that is rich in Cl^- , causing selective loss of this ion as well as H^+ and K^+ losses. The resultant metabolic alkalosis is ameliorated by K^+ and Cl^- administration, but correction is difficult because of continuing losses. Interestingly, the volume of diarrhea is reduced dramatically by proton pump inhibition, which reduces gastric Cl^- secretion and presumably reduces Cl^- delivery to the small intestine.²⁰

Other Causes of Excessive Chloride Losses

Villous adenomas occur in the distal colon and typically secrete 1 to 3 liters of fluid a day that is rich in Na^+ , Cl^- , and K^+ . Because the volume of secreted fluid is relatively low, these tumors are only occasionally associated with metabolic alkalosis, and the disorder, when it is present, is usually mild.²¹ Cystic fibrosis is characterized by high sweat $[\text{Cl}^-]$, and with excessive sweating, Cl^- losses can be large enough to cause metabolic alkalosis. In children and adolescents, this acid-base disorder can be the presenting symptom.²² Patients with high-volume ileostomy

losses can sometimes develop severe metabolic alkalosis.²³ In these cases, the fluid contains abnormally high concentrations of Na^+ and Cl^- . The use of gastric tissue to augment bladder size (gastrocystoplasty) can occasionally lead to transient metabolic alkalosis as a result of gastrin-induced Cl^- secretion into the urine.²⁴

Severe K^+ Deficiency

In patients with severe K^+ depletion (serum $[\text{K}^+] < 2 \text{ mmol/l}$), metabolic alkalosis can be sustained despite Cl^- administration.¹⁰ Chloride resistance in this setting is probably due to impairment of renal Cl^- reabsorption (see earlier discussion). Even partial repletion of K^+ stores rapidly reverses this problem and makes the alkalosis Cl^- responsive.

Corticosteroid and Apparent Corticosteroid-Induced Metabolic Alkalosis

Figure 13.7 lists the causes of these forms of metabolic alkalosis.

Mineralocorticoid Excess

Aldosterone and other mineralocorticoids cause metabolic alkalosis by stimulating both the H^+ -ATPase and epithelial Na^+ channel (ENaC) in the collecting duct (see Figs. 13.1 and 13.4). The resultant Na^+ retention causes hypertension and also ensures continued delivery of Na^+ to the distal nephron, facilitating continued H^+ and K^+ secretion. The metabolic alkalosis is typically mild (serum $[\text{HCO}_3^-]$ 30 to 35 mmol/l) and is associated with more severe hypokalemia (K^+ often $< 3 \text{ mmol/l}$) than is observed in most Cl^- -responsive causes.^{9,13} Primary hyperaldosteronism is by far the most common cause of this form of metabolic alkalosis (see Chapter 38), but it can also occur with rarer hereditary defects in cortisol synthesis or in the regulation of aldosterone secretion (see Fig. 13.7). Glucocorticoid-remediable aldosteronism (see Chapter 38) is caused by a mutation that results in stimulation of aldosterone secretion by adrenocorticotrophic hormone (ACTH) rather than by angiotensin.²⁵ Fludrocortisone, an oral mineralocorticoid drug, as well as inhaled 9 α -fluoroprednisolone can induce metabolic alkalosis if it is used inappropriately. Corticosteroids, when they are administered in very high doses, increase renal K^+ excretion nonspecifically and produce a mild increase in serum $[\text{HCO}_3^-]$.

Apparent Mineralocorticoid Excess Syndromes

Several inherited abnormalities produce a metabolic alkalosis that is clinically indistinguishable from hyperaldosteronism but without measurable aldosterone (see Chapter 47). Liddle syndrome results from a genetic mutation that prevents the removal of epithelial Na^+ channels from the urinary membrane of collecting duct epithelial cells (see Fig. 13.4).²⁶ As a result, Na^+ reabsorption cannot be downregulated, causing the same cascade of events seen in hyperaldosteronism. Because continuous stimulation of Na^+ reabsorption expands ECF volume, however, aldosterone levels are vanishingly low. In another rare familial disorder, termed the syndrome of apparent mineralocorticoid excess, a mutation inactivates 11 β -hydroxysteroid dehydrogenase, an enzyme adjacent to the mineralocorticoid receptor that rapidly converts cortisol to cortisone, minimizing cortisol binding to this receptor.²⁷ When the enzyme is inactivated, cortisol activates the receptor, stimulating Na^+ reabsorption and K^+ secretion and producing Cl^- -resistant metabolic alkalosis and hypertension with low aldosterone levels. Glycyrrhizic acid (a component of natural licorice), carbenoxolone, and gossypol

Causes of Metabolic Alkalosis Associated with Alkali Administration	
Renal Status	Causes
Normal renal function (only in association with K^+ depletion or low $NaCl$ intake)	Alkali intake: $NaHCO_3$, citrate, lactate, acetate, amino acid anions

Figure 13.8 Causes of metabolic alkalosis associated with alkali administration.

(an agent that inhibits spermatogenesis) inhibit the activity of 11β -hydroxysteroid dehydrogenase and can cause the same clinical picture.⁹

Alkali Administration

Exogenous alkali produces metabolic alkalosis in individuals with deficient body K^+ or Cl^- stores by impaired renal HCO_3^- excretion (Fig. 13.8; see earlier discussion).¹¹ In acute or chronic renal impairment, alkali administration or ingestion produces metabolic alkalosis independent of K^+ and Cl^- stores because the excess alkali cannot be excreted.¹² Milk-alkali syndrome is characterized by the concomitant presence of metabolic alkalosis and renal insufficiency, brought on by the ingestion of $NaHCO_3$ in combination with excess calcium (either in milk or as $CaCO_3$).^{28,29} In this disorder, renal damage is caused by calcium deposition (facilitated by an alkaline urine). The renal damage in turn facilitates the development of metabolic alkalosis if alkali ingestion continues. Metabolic alkalosis is usually mild in these patients unless they develop concomitant vomiting. In hospitalized patients with renal failure, a wide variety of alkali sources or alkali precursors can cause metabolic alkalosis (Fig. 13.9). Although it is only rarely administered now, aluminum hydroxide in combination with sodium polystyrene sulfonate (Kayexalate) can cause metabolic alkalosis because aluminum binds to the resin in exchange for Na^+ . As a result, the HCO_3^- normally secreted into the duodenum is not titrated by H^+ (which was neutralized by the aluminum hydroxide), nor does it form an insoluble salt with aluminum. Instead, it is completely reabsorbed from the gut, increasing serum $[HCO_3^-]$.³⁰

Other Causes

Refeeding after starvation causes an abrupt increase in serum $[HCO_3^-]$ from the low levels characteristic of the fasting state. In some instances, serum $[HCO_3^-]$ increases transiently above normal, causing a mild metabolic alkalosis. The causes are multiple, including HCO_3^- generation from metabolism of accumulated organic anions and K^+ and Cl^- depletion. Administration of vitamin D causes a small but significant increase in serum $[HCO_3^-]$.^{31,32} Hyperparathyroidism in the clinic, however, is not associated with metabolic alkalosis. Hypercalcemia and vitamin D intoxication have been associated with metabolic alkalosis, but in most instances, the alkalosis can be explained by the vomiting that characteristically accompanies these disorders. High aldosterone levels induced by hyperreninemia in renovascular or

Potential Sources of Alkali	
Alkali/Alkali Precursor	Source
Bicarbonate	$NaHCO_3$: pills, intravenous solutions Proprietary brands, e.g., Alka-Seltzer Baking soda $KHCO_3$: pills, oral solutions
Lactate	Ringer's solution, peritoneal dialysis solutions
Acetate Glutamate Propionate	Parenteral nutrition
Citrate	Blood products, plasma exchange, K^+ supplements, alkalinizing agents
Calcium compounds (alkalinizing effect minimal when given orally) Acetate Citrate Carbonate	Calcium supplements, phosphate binders

Figure 13.9 Potential sources of alkali.

malignant hypertension are associated with hypokalemia and, occasionally, with very minor increases in serum $[HCO_3^-]$.

CLINICAL MANIFESTATIONS

Mild to moderate metabolic alkalosis is well tolerated, with few clinically important adverse effects. Patients with serum $[HCO_3^-]$ levels as high as 40 mmol/l are usually asymptomatic. The adverse effect of most concern is hypokalemia, which increases the likelihood of cardiac arrhythmias in patients with ischemic heart disease.³³ With more severe metabolic alkalosis (serum $[HCO_3^-] >45$ mmol/l), arterial P_{O_2} often decreases to less than 50 mm Hg (<6.65 kPa) secondary to hypoventilation, and ionized calcium decreases (due to alkalemia). Patients with serum $[HCO_3^-]$ greater than 50 mmol/l may develop seizures, tetany, delirium, or stupor. These changes in mental status are probably multifactorial in origin, due to alkalemia, hypokalemia, hypocalcemia, and hypoxemia.

DIAGNOSIS

Diagnosis of metabolic alkalosis involves three steps (Fig. 13.10). The first step, detection, is most often based on the finding of an elevated serum [total CO_2]. The second step is evaluation of the secondary response (hypoventilation), excluding the possibility that a respiratory acid-base abnormality is also present. This step requires measurement of arterial pH and P_{CO_2} . The third step is determination of the cause.

Serum [total CO_2] above 30 mmol/l in association with hypokalemia is virtually pathognomonic of metabolic alkalosis. The only other cause of an elevated serum $[HCO_3^-]$ is chronic respiratory acidosis, and hypokalemia is not a feature of this disorder (see Chapter 14). Because the diagnosis is usually evident and the disorder is almost always uncomplicated, one need not measure arterial pH and P_{CO_2} in most patients.

If the alkalosis is severe (serum $[HCO_3^-] >40$ mmol/l), if the cause of the elevated $[HCO_3^-]$ is unclear, or if a mixed acid-base disorder is suspected, however, one should always measure pH

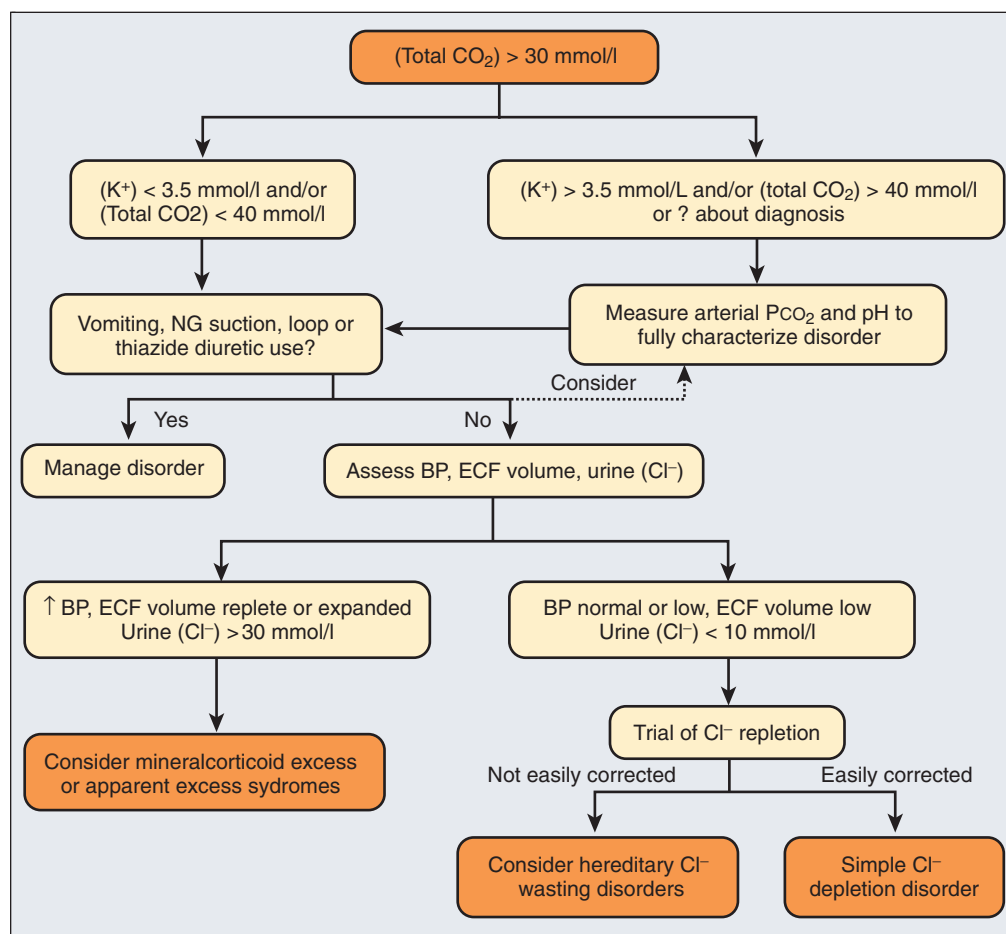

Figure 13.10 Approach to diagnosis of metabolic alkalosis. If the increase in [total CO₂] (or serum [HCO₃⁻]) is mild and hypokalemia is present, arterial gas measurements are usually not necessary, and a simple algorithm can be used to diagnose Cl⁻-responsive and Cl⁻-resistant metabolic alkalosis. If hypokalemia is not present, if the increase in serum [total CO₂] is severe, or if there is a question about the diagnosis, arterial measurement of pH and PCO₂ is recommended to determine whether the condition is due to metabolic alkalosis, respiratory acidosis, or a mixed disorder. BP, blood pressure; ECF, extracellular fluid; NG, nasogastric.

and PCO₂ to fully characterize the disorder (see Fig. 13.10). These measurements confirm the presence of alkalosis and allow an estimation of whether the degree of hypoventilation is appropriate for the serum [HCO₃⁻] (see earlier equation). A major deviation in PCO₂ from the expected value indicates the presence of a complicating respiratory acid-base disorder (either respiratory acidosis or alkalosis; see Chapter 14). The anion gap, $[Na^+] - ([Cl^-] + [HCO_3^-])$, is not increased in mild to moderate metabolic alkalosis, but it can be increased by as much as 3 to 5 mmol/l when alkalosis is severe. If the anion gap is more than 20 mmol/l, the disorder is most likely complicated by a superimposed metabolic acidosis (see Chapter 12).

In most instances, the third step, elucidation of the cause, is also straightforward. In more than 95% of cases, metabolic alkalosis is caused either by diuretic use or by Cl⁻ losses from the gastrointestinal tract. This is usually easily obtained from the history, and attention can be directed toward the appropriate treatment. If the cause is unclear from the history, measurement of urine [Cl⁻] can help. Unless the patient has recently taken a diuretic agent, urine [Cl⁻] should be less than 10 mmol/l if the metabolic alkalosis is due to Cl⁻ depletion. A confounding problem can be self-induced vomiting (bulimia) or the surreptitious use of diuretics, which presents the greater diagnostic dilemma because continued diuretic-induced Cl⁻ excretion may lead one to undertake an extensive workup for rarer forms of metabolic alkalosis. Urinary screens for specific diuretic compounds may be necessary to establish the correct diagnosis. In bulimic patients, urine Cl⁻ excretion should be low (spot urine

[Cl⁻] < 10 mmol/l). If the cause is not apparent from this analysis, rarer forms of metabolic alkalosis caused by tubular transport abnormalities should be considered. In these forms of metabolic alkalosis, urine [Cl⁻] is typically greater than 30 mmol/l.

In the patient with hypertension and adequate chloride intake, who is not taking any diuretic agents, the most common cause of metabolic alkalosis is primary hyperaldosteronism. Measurement of serum renin and serum or urine aldosterone levels can distinguish mineralocorticoid excess syndromes from the rarer syndromes of apparent mineralocorticoid excess (see Fig. 13.7). The details of such a workup are presented in Chapter 38. In the normotensive or hypotensive patient who is not taking any diuretic agents and has metabolic alkalosis despite adequate chloride intake, the diagnosis of either Bartter or Gitelman's syndrome should be considered. Aldosterone and renin levels are not helpful in making these diagnoses because the levels can be low or high, depending on the patient's ECF volume at the time of measurement. Familial genetic studies can establish these diagnoses with high specificity.

TREATMENT

Chloride Depletion Alkalosis

In the patient with metabolic alkalosis due to nasogastric drainage or vomiting, ECF volume depletion is always a concomitant feature, and treatment is straightforward. Administration of intravenous NaCl will correct both the alkalosis and the volume

depletion. Potassium losses should also be replaced by oral or intravenous KCl. Typically, the K^+ deficit is 200 to 400 mmol in patients with mild to moderate metabolic alkalosis induced by upper gastrointestinal Cl^- losses. When nasogastric drainage must be continued, H^+ and Cl^- losses can be reduced by administration of drugs that inhibit gastric acid secretion, such as famotidine and omeprazole. In contrast to patients with upper gastrointestinal losses, NaCl administration is not usually required in patients with metabolic alkalosis caused by diuretics unless clinical signs of volume depletion are present. Potassium chloride supplements should be given to minimize K^+ depletion as well as the metabolic alkalosis. The addition of a potassium-sparing diuretic, such as amiloride, triamterene, spironolactone, or eplerenone, can assist in minimizing these abnormalities. Complete repair of diuretic-induced metabolic alkalosis is often difficult because of continued Cl^- and K^+ losses. Fortunately, such a therapeutic goal is not necessary in most instances. A mild metabolic alkalosis is well tolerated, with no clinically significant adverse effects. If possible, the diuretic should be discontinued and then the disorder will resolve so long as the diet contains adequate K^+ and Cl^- .

The metabolic alkalosis (and hypokalemia) seen in Bartter and Gitelman's syndromes is the most difficult to correct. In addition to oral KCl supplements (and magnesium supplements in Gitelman's syndrome), nonsteroidal anti-inflammatory drugs have been used with moderate success. These drugs minimize renal Cl^- losses.

Corticosteroid and Apparent Corticosteroid-Induced Metabolic Alkalosis

Management of metabolic alkalosis caused by corticosteroids or tubular transport abnormalities that mimic corticosteroid excess depends on the underlying cause. If the alkalosis is caused by an adrenal adenoma, the disorder is corrected by surgical removal of the tumor (see Chapter 38). In other forms of primary hyperaldosteronism, the alkalosis can be minimized by dietary NaCl restriction and by aggressive replacement of body K^+ stores with supplemental KCl. Spironolactone or eplerenone, competitive inhibitors of aldosterone, can also correct the disorder. In glucocorticoid-remediable aldosteronism, the disorder is corrected by dexamethasone administration, which suppresses ACTH secretion and thereby reduces aldosterone secretion. In the hereditary forms of apparent mineralocorticoid excess (Liddle syndrome and 11β -hydroxysteroid dehydrogenase deficiency), amiloride is the most effective treatment.

Alkali Ingestion

Treatment here is directed at identification and discontinuation of the offending alkali (see Fig. 13.9). In the intensive care unit, care should be taken to look for sources of exogenous alkali. A common offender is acetate used as a replacement for Cl^- in parenteral nutrition solutions.

SPECIAL PROBLEMS IN MANAGEMENT

Management of metabolic alkalosis is a more difficult undertaking in patients with severe congestive heart failure or renal failure. In patients with heart failure and fluid overload who still have renal function, acetazolamide can be used to reduce serum $[HCO_3^-]$. This carbonic anhydrase inhibitor blocks H^+ -linked Na^+ reabsorption, leading to excretion of both Na^+ and HCO_3^- .

Acetazolamide decreases extracellular volume and lowers serum $[HCO_3^-]$, but it stimulates K^+ excretion, exacerbating hypokalemia. When it is used, it should be accompanied by aggressive K^+ replacement therapy.

In patients with renal failure, serum $[HCO_3^-]$ can be reduced in a timely fashion by the appropriate form of renal replacement therapy. Continuous venovenous hemofiltration can remove as much as 20 to 30 l/day of an ultrafiltrate of plasma, and the replacement solution can be modified to control electrolyte composition. Serum $[HCO_3^-]$ can also be lowered rapidly by continuous slow low-efficiency dialysis, with the dialysate $[HCO_3^-]$ adjusted to 23 mmol/l. Standard hemodialysis or peritoneal dialysis is less useful because these treatments are designed to add alkali to the blood, and the alkali concentration in the dialysate is set at 35 to 40 mmol/l.

If renal replacement therapy cannot be instituted, titration with HCl is an alternative therapy. This approach is limited by the concentration of HCl that can be administered without producing hemolysis or venous coagulation. Although some investigators have used higher concentrations, the recommended safe level of H^+ is 100 mmol/l (0.1 N HCl). Even at this concentration, HCl must be administered through a central vein. Because the apparent space of distribution of HCO_3^- is approximately 50% of body weight, 350 mmol of H^+ is required to reduce serum $[HCO_3^-]$ by 10 mmol/l in a 70-kg patient. The volume of fluid required for this titration with use of HCl, unfortunately, is 3.5 liters. Ammonium chloride (NH_4Cl) and arginine monohydrochloride are no longer recommended for the treatment of metabolic alkalosis because they both cause life-threatening problems; the former can cause NH_3 intoxication, and the latter can cause severe hyperkalemia.

Respiratory Acidosis, Respiratory Alkalosis, and Mixed Disorders

Horacio J. Adrogué, Nicolaos E. Madias

Deviations of systemic acidity in either direction can have adverse consequences and, when severe, can be life-threatening. Therefore, it is essential for the clinician to recognize and properly diagnose acid-base disorders, to understand their impact on organ function, and to be familiar with their treatment and the potential complications of treatment.^{1,2}

RESPIRATORY ACIDOSIS (PRIMARY HYPERCAPNIA)

Definition

Respiratory acidosis is the acid-base disturbance initiated by an increase in CO₂ tension of body fluids and in whole-body CO₂ stores. The secondary increment in plasma bicarbonate [HCO₃⁻] observed in acute and chronic hypercapnia is an integral part of the respiratory acidosis.³ The level of arterial CO₂ tension (Paco₂) is above 45 mm Hg (to convert values from mm Hg to kP, multiply by 0.1333) in patients with simple respiratory acidosis (measured at rest and at sea level). An element of respiratory acidosis may still occur with lower Paco₂ in patients residing at high altitude (e.g., 4000 m or 13,000 ft) or with metabolic acidosis, in whom a normal Paco₂ is inappropriately high for this condition.⁴ Another special case of respiratory acidosis is the presence of arterial eucapnia, or even hypocapnia, occurring together with severe venous hypercapnia, in patients having an acute, profound decrease in cardiac output but relative preservation of respiratory function.^{5,6} This disorder is known as pseudorespiratory alkalosis and is discussed under respiratory alkalosis.

Etiology and Pathogenesis

The ventilatory system is responsible for eucapnia by adjustment of alveolar minute ventilation (V_A) to match the rate of CO₂ production. Its main elements are the respiratory pump, which generates a pressure gradient responsible for airflow, and the loads that oppose such action.

Carbon dioxide retention can occur from an imbalance between the strength of the respiratory pump and the extent of respiratory load (Fig. 14.1). When the respiratory pump is unable to balance the opposing load, respiratory acidosis develops. Respiratory acidosis may be acute or chronic (Figs. 14.2 and 14.3). Life-threatening acidemia of respiratory origin can occur during severe, acute respiratory acidosis or during respiratory decompensation in patients with chronic hypercapnia.

A simplified form of the alveolar gas equation at sea level and on breathing of room air (F_{IO2}, 21%) is as follows:

$$PAO_2 = 150 - 1.25 P_{ACO_2}$$

where PAO₂ is alveolar O₂ tension (mm Hg). This equation demonstrates that patients breathing room air cannot reach Paco₂ levels much greater than 80 mm Hg (10.6 kP) because the hypoxemia that would occur at greater values is incompatible with life. Therefore, extreme hypercapnia occurs only during O₂ therapy, and severe CO₂ retention is often the result of uncontrolled O₂ administration.

Secondary Physiologic Response

Adaptation to acute hypercapnia elicits an immediate increment in plasma HCO₃⁻ concentration due to titration of non-HCO₃⁻ body buffers; such buffers generate HCO₃⁻ by combining with H⁺ derived from the dissociation of carbonic acid:

where B⁻ refers to the base component and HB refers to the acid component of non-HCO₃⁻ buffers. This adaptation is completed within 5 to 10 minutes from the increase in Paco₂, and assuming a stable level of hypercapnia, no further change in acid-base equilibrium is detectable for a few hours.⁷ Moderate hypoxemia does not alter the adaptive response to acute respiratory acidosis. However, preexisting hypobicarbonatemia (whether it is caused by metabolic acidosis or chronic respiratory alkalosis) enhances the magnitude of the HCO₃⁻ response to acute hypercapnia; this response is diminished in hyperbicarbonatemic states (whether they are caused by metabolic alkalosis or chronic respiratory acidosis).^{8,9}

The adaptive increase in plasma HCO₃⁻ concentration observed in acute hypercapnia is amplified greatly during chronic hypercapnia as a result of HCO₃⁻ generation by the kidney. In addition, the renal response to chronic hypercapnia includes a reduction in the rate of Cl⁻ reabsorption, resulting in depletion of body Cl⁻ stores. Complete adaptation to chronic hypercapnia requires 3 to 5 days.⁷ Quantitative aspects of the secondary physiologic responses to acute and chronic hypercapnia are depicted in Figure 14.4. The renal response to chronic hypercapnia is not altered appreciably by dietary Na⁺ or Cl⁻ restriction, moderate K⁺ depletion, alkali loading, or moderate hypoxemia. However, recovery from chronic hypercapnia is crippled by a diet deficient in Cl⁻; in this circumstance, despite correction of the level of Paco₂, plasma [HCO₃⁻] remains elevated so long as the state of Cl⁻ deprivation persists, leading to posthypercapnic metabolic alkalosis.

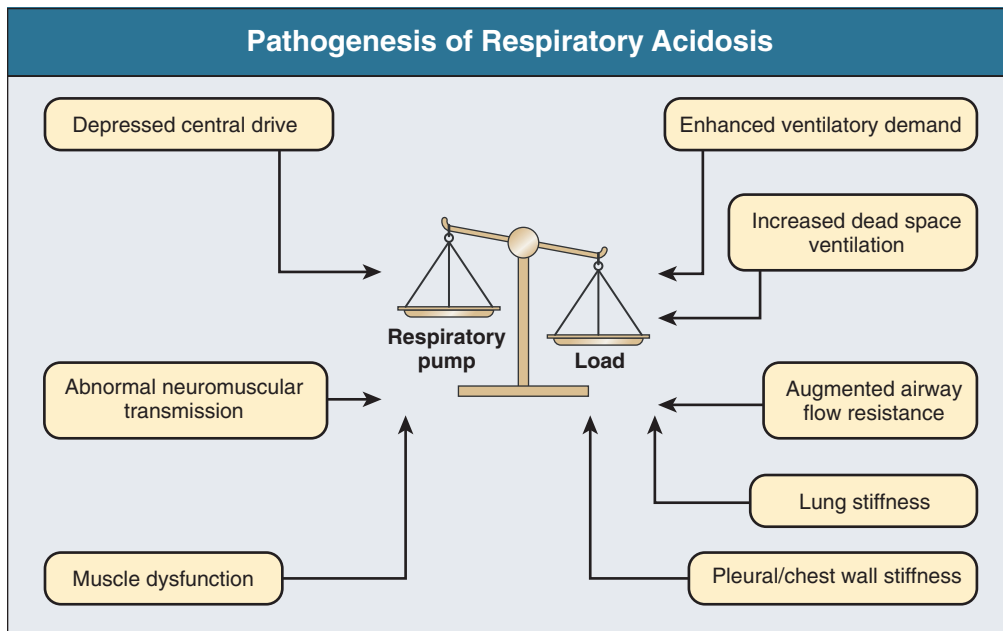

Figure 14.1 Pathogenesis of respiratory acidosis.

Clinical Manifestations

Because clinical hypercapnia almost always occurs in association with hypoxemia, it is often difficult to determine whether a specific manifestation is the consequence of the elevated P_{aCO_2} or the reduced P_{aO_2} . Nevertheless, one should bear in mind several characteristic manifestations of neurologic or cardiovascular dysfunction to diagnose the condition accurately and to treat it effectively.^{4,7}

Neurologic Symptoms

Acute hypercapnia is often associated with marked anxiety, severe breathlessness, disorientation, confusion, incoherence, and combativeness. A narcotic-like effect is not uncommon in patients with chronic hypercapnia, and drowsiness, decreased alertness, inattention, forgetfulness, loss of memory, irritability, confusion, and somnolence can be observed. Motor disturbances, including tremor, myoclonic jerks, and asterixis, are frequently observed with both acute and chronic hypercapnia. Sustained myoclonus and seizure activity can also develop. Signs and symptoms of increased intracranial pressure (pseudotumor cerebri) are occasionally evident in patients with either acute or chronic hypercapnia, and they appear to be related to the vasodilating effects of CO_2 on cerebral blood vessels. Headache is a frequent complaint. Blurring of the optic discs and frank papilledema can be found when hypercapnia is severe. Hypercapnic coma characteristically occurs in patients with acute exacerbations of chronic respiratory insufficiency who are treated injudiciously with high-flow O_2 .

Cardiovascular Symptoms

Acute hypercapnia of mild to moderate degree is usually characterized by warm and flushed skin, bounding pulse, sweating, increased cardiac output, and normal or increased blood pressure. By comparison, severe hypercapnia might be attended by decreases in both cardiac output and blood pressure. Cardiac arrhythmias occur frequently in patients with either acute or chronic hypercapnia, especially those receiving digoxin.

Renal Symptoms

Mild to moderate hypercapnia results in renal vasodilation, but acute increments in P_{aCO_2} to levels above 70 mm Hg (9.3 kPa) can induce renal vasoconstriction and hypoperfusion. Salt and water retention commonly attend sustained hypercapnia, especially in the presence of cor pulmonale. In addition to the effects of heart failure on the kidney, multiple other factors might be at play, including the prevailing stimulation of the sympathetic nervous system and the renin-angiotensin-aldosterone axis, the increased renal vascular resistance, and the elevated levels of antidiuretic hormone and cortisol.

Diagnosis

Whenever CO_2 retention is suspected, arterial blood gas values should be obtained.¹⁰ If the patient's acid-base profile reveals hypercapnia in association with acidemia, at least an element of respiratory acidosis must be present. However, hypercapnia can be associated with a normal or even an alkaline pH if certain additional acid-base disorders are also present. Information from the patient's history, physical examination, and ancillary laboratory data should be used to assess whether part or all of the increase in P_{aCO_2} reflects an adaptive response to metabolic alkalosis rather than being primary in origin.

Treatment

As previously noted, CO_2 retention, whether it is acute or chronic, is always associated with hypoxemia in patients breathing room air. Consequently, O_2 administration represents a critical element in the management of respiratory acidosis.^{1,11} However, supplemental O_2 may lead to worsening hypercapnia, especially in patients with chronic obstructive pulmonary disease (COPD). Although a depressed respiratory drive in CO_2 retention seems to play a role, other factors might account for the worsening hypercapnia in response to supplemental O_2 therapy. These include an increase in dead space ventilation and

Secondary Response to Alterations in Acid-Base Status			
Condition	Initiating Mechanism	Expected Response: Change in $[\text{HCO}_3^-]$ or PaCO_2	Maximal Level of Response
Respiratory acidosis	Increase in PaCO_2		
Acute		Increase in $[\text{HCO}_3^-] \approx 0.1 \text{ PaCO}_2$	30 mmol/l
Chronic		Increase in $[\text{HCO}_3^-] \approx 0.3 \text{ PaCO}_2$	45 mmol/l
Respiratory alkalosis	Decrease in PaCO_2		
Acute		Decrease in $[\text{HCO}_3^-] \approx 0.2 \text{ PaCO}_2$	16–18 mmol/l
Chronic		Decrease in $[\text{HCO}_3^-] \approx 0.4 \text{ PaCO}_2$	12–15 mmol/l
Metabolic acidosis	Decrease in $[\text{HCO}_3^-]_p$	Decrease in $\text{PaCO}_2 \approx 1.2 [\text{HCO}_3^-]$	10 mm Hg (1.3 kPa)
Metabolic alkalosis	Increase in $[\text{HCO}_3^-]_p$	Increase in $\text{PaCO}_2 \approx 0.7 [\text{HCO}_3^-]$	65 mm Hg (8.7 kPa)

Figure 14.4 Secondary response to alterations in acid-base status.

ventilation/perfusion (\dot{V}/\dot{Q}) mismatch due to the loss of hypoxic pulmonary vasoconstriction and the Haldane effect (the decreased hemoglobin affinity for CO_2 in the presence of increased O_2 saturation), which mandates an increase in ventilation to eliminate the excess CO_2 .⁷

The management of acute respiratory acidosis and chronic respiratory acidosis is presented in Figures 14.5 and 14.6. Whenever possible, treatment must be directed at removal or amelioration of the underlying cause. Immediate therapeutic efforts should focus on securing a patent airway and restoring adequate oxygenation by delivery of an O_2 -rich inspired mixture. Supplemental oxygen can be administered to the spontaneously breathing patient with nasal cannulas, Venturi masks, or non-rebreathing masks. Oxygen flow rates up to 5 l/min can be used with nasal cannulas; each increment of 1 l/min increases the FIO_2 by

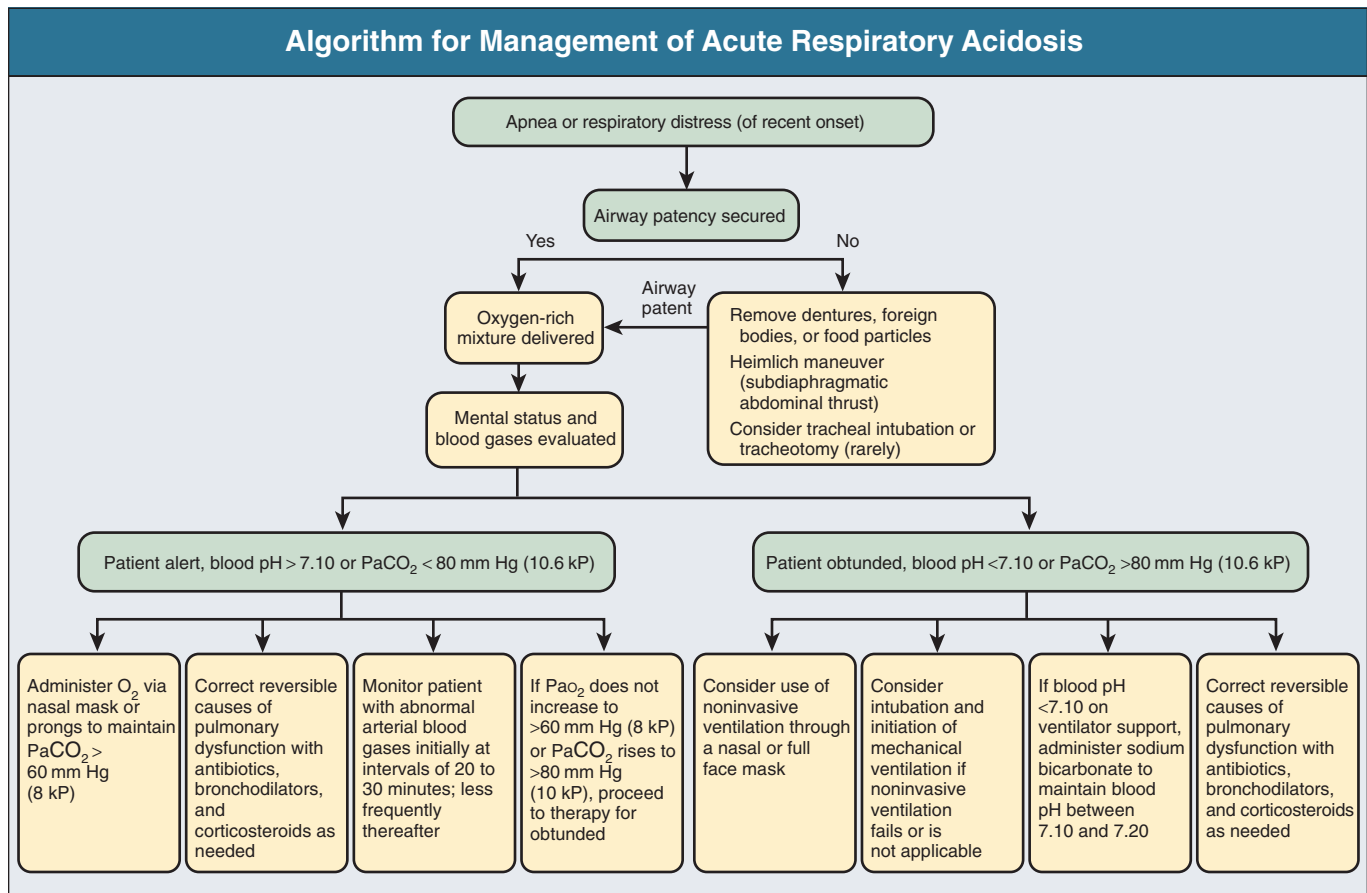

Figure 14.5 Algorithm for the management of acute respiratory acidosis.

approximately 4%. Venturi masks, calibrated to deliver F_{IO_2} between 24% and 50%, are most useful in patients with COPD because the P_{O_2} can be titrated, thus minimizing the risk of CO_2 retention. Oxygen saturation of hemoglobin of approximately 80% to 90% can be achieved with nonbreathing masks.

If the target P_{O_2} is not achieved with these measures and the patient is conscious, cooperative, hemodynamically stable, and able to protect the lower airway, a method of noninvasive ventilation through a mask can be used (e.g., bilevel positive airway pressure [BiPAP]). With BiPAP, the inspiratory-pressure support decreases the work of breathing, and the expiratory-pressure support improves gas exchange by preventing alveolar collapse.

Endotracheal intubation and mechanical ventilatory support should be initiated if adequate oxygenation cannot be secured by noninvasive measures, if progressive hypercapnia or obtundation develops, or if the patient is unable to cough and clear secretions. Minute ventilation should be raised so that the P_{aCO_2} gradually returns to near its long-term baseline and excretion of excess HCO_3^- by the kidneys is accomplished (assuming that Cl^- is provided). By contrast, overly rapid reduction in the P_{aCO_2} risks the development of posthypercapnic alkalosis, with potentially serious consequences. Should posthypercapnic alkalosis develop, it can be ameliorated by providing Cl^- , usually as the potassium salt, and administering the HCO_3^- -wasting diuretic acetazolamide at doses of 250 to 500 mg once or twice daily. Vigorous treatment of pulmonary infections, bronchodilator therapy, and

removal of secretions can offer considerable benefit. Naloxone will reverse the suppressive effect of narcotic agents on ventilation. Avoidance of tranquilizers and sedatives, gradual reduction of supplemental oxygen (aiming at a P_{aO_2} of about 60 mm Hg [8 kPa]), and treatment of a superimposed metabolic alkalosis will optimize the ventilatory drive.

Mechanical ventilation with tidal volumes of 10 to 15 ml/kg body weight often leads to alveolar overdistention and volutrauma. Therefore, an alternative approach called permissive hypercapnia (or controlled mechanical hypoventilation) has been successfully applied to prevent barotrauma and cardiovascular collapse.^{4,12} In this form of treatment, lower tidal volumes of less than 6 ml/kg body weight and lower peak inspiratory pressures are used. Further, P_{aCO_2} is allowed to increase but rarely exceeds 80 mm Hg, and blood pH can decrease to as low as 7.00 to 7.10, while adequate oxygenation is maintained. Because the patients commonly require neuromuscular blockade as well, accidental disconnection from the ventilator can cause sudden death. Contraindications to permissive hypercapnia include cerebrovascular disease, brain edema, increased intracranial pressure, convulsions, depressed cardiac function, arrhythmias, and severe pulmonary hypertension. Correction of acidemia attenuates the adverse hemodynamic effects of permissive hypercapnia.¹³ It appears prudent, although still controversial, to keep the blood pH at approximately 7.30 by the administration of intravenous alkali when controlled hypoventilation is prescribed.^{1,14}

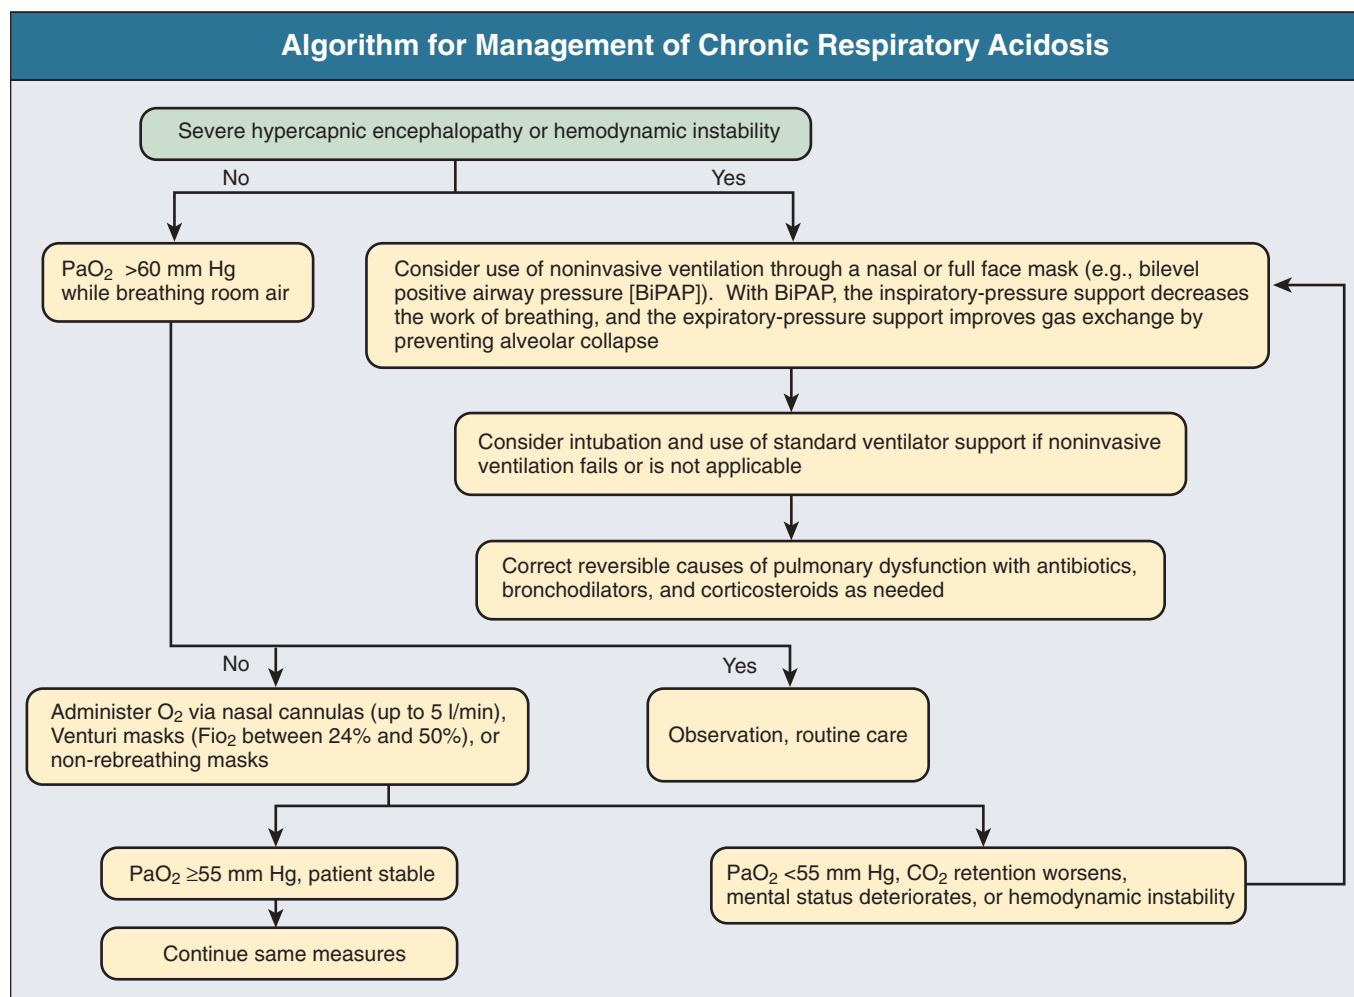

Figure 14.6 Algorithm for the management of chronic respiratory acidosis.

RESPIRATORY ALKALOSIS (PRIMARY HYPOCAPNIA)

Definition

Respiratory alkalosis is the acid-base disturbance initiated by a reduction in CO_2 tension of body fluids. The secondary decrease in plasma HCO_3^- concentration observed in acute and chronic hypocapnia is an integral part of the respiratory alkalosis. Whole-body CO_2 stores are decreased and Paco_2 is less than 35 mm Hg (4.7 kP) in patients with simple respiratory alkalosis who are at rest and at sea level. An element of respiratory alkalosis may still occur with higher levels of Paco_2 in patients with metabolic alkalosis, in whom a normal Paco_2 is inappropriately low for this primary metabolic disorder.

Etiology and Pathogenesis

Respiratory alkalosis is the most frequent acid-base disorder encountered because it occurs in normal pregnancy and with high-altitude residence.^{2,15} It is also the most common acid-base abnormality in critically ill patients, occurring either as the simple disorder or as a component of mixed disturbances; indeed, in such patients, its presence may constitute a grave prognostic sign, especially if Paco_2 levels are below 20 to 25 mm Hg (2.7 to 3.3 kP). The presence of hypocapnia signifies transient or

persistent alveolar hyperventilation relative to the prevailing CO_2 production, thus leading to negative CO_2 balance; primary hypocapnia might also originate from the extrapulmonary elimination of CO_2 by dialysis or other extracorporeal circulation (e.g., heart-lung machine).

Figure 14.7 gives the major causes of respiratory alkalosis.⁶ In most patients, primary hypocapnia reflects alveolar hyperventilation due to increased ventilatory drive. This is a consequence of signals arising from the lung, the peripheral chemoreceptors (carotid and aortic), or the brainstem chemoreceptors or influences originating in other centers of the brain.

The response of the brainstem chemoreceptors to CO_2 can be augmented by systemic diseases (e.g., liver disease, sepsis), pharmacologic agents, and volition. Hypoxemia is a major stimulus of alveolar ventilation, but Pao_2 values below 60 mm Hg (8 kP) are required to elicit this effect consistently. Not uncommonly, alveolar hyperventilation is the result of maladjusted mechanical ventilators, psychogenic hyperventilation, and lesions involving the central nervous system.

In states of severe circulatory failure, arterial hypocapnia may coexist with venous and therefore tissue hypercapnia; under these conditions, the body CO_2 stores have been enriched so that there is respiratory acidosis rather than respiratory alkalosis. This entity, which we have termed pseudorespiratory alkalosis, develops in patients with profound depression of cardiac function and pulmonary perfusion but relative preservation of alveolar

Causes of Respiratory Alkalosis

Figure 14.7 Causes of respiratory alkalosis.

ventilation, including patients with advanced circulatory failure and those undergoing cardiopulmonary resuscitation. The severely reduced pulmonary blood flow limits the CO₂ delivered to the lungs for excretion, thereby increasing the venous Pco₂. However, the increased ventilation/perfusion ratio causes a larger than normal removal of CO₂ per unit of blood traversing the pulmonary circulation, thereby giving rise to arterial eucapnia or frank hypocapnia. A progressive widening of the arteriovenous difference in pH and Pco₂ develops in two settings of cardiac dysfunction, circulatory failure and cardiac arrest (Fig. 14.8). In both situations, there is severe tissue O₂ deprivation, and it can be completely disguised by the reasonably preserved arterial O₂ values. Appropriate monitoring of acid-base composition and oxygenation in patients with advanced cardiac dysfunction requires mixed (or central) venous blood sampling in addition to the sampling of arterial blood.

Secondary Physiologic Response

Adaptation to acute hypocapnia is characterized by an immediate decrement in plasma HCO₃⁻ that results totally from nonrenal mechanisms and is explained principally by alkaline titration of the non-HCO₃⁻ body buffers (see second equation and Fig. 14.4). This adaptation is completed within 5 to 10 minutes of the onset of hypocapnia, and if there is no further change in Paco₂, no additional detectable changes in acid-base equilibrium occur for a period of several hours.

Figure 14.8 Arteriovenous differences in pH and PCO₂ in patients with different hemodynamic conditions.

Adaptation to chronic hypocapnia entails an additional, larger decrease in plasma HCO₃⁻ as a consequence of renal adjustments that reflect a dampening of H⁺ secretion by the renal tubule.⁷ Approximately 2 to 3 days are required for completion of the adaptation to chronic hypocapnia. Quantitative aspects of the secondary physiologic responses to acute and chronic hypocapnia are shown in Figure 14.4.

Clinical Manifestations

A rapid decrease in Paco₂ to half normal values or lower is typically accompanied by numbness and paresthesias of the extremities, chest discomfort, circumoral numbness, lightheadedness, and mental confusion. Muscle cramps, increased deep tendon reflexes, carpopedal spasm, and generalized seizures occur infrequently. Cerebral vasoconstriction and reduced cerebral blood flow have been well documented during acute hypocapnia; in severe cases, cerebral blood flow might reach values below 50% of normal. Hypocapnia can have deleterious effects on the brain of premature infants; in patients with traumatic brain injury, acute stroke, or general anesthesia; and after sudden exposure to very high altitude.¹⁶ Long-term neurologic sequelae can develop when immature brains are exposed to Paco₂ levels below 15 mm Hg (2 kPa) for even short periods. Furthermore, abrupt correction of hypocapnia in these patients leads to cerebral vasodilation, which might cause reperfusion injury or intraventricular hemorrhage.

Brain injury due to hypocapnia probably results from cerebral ischemia. Other factors include hypocapnia *per se*, alkalemia,

pH-induced shift of the oxyhemoglobin dissociation curve, decrements in the levels of ionized calcium and potassium, depletion of the antioxidant glutathione by cytotoxic excitatory amino acids, increases in anaerobic metabolism, cerebral oxygen demand, neuronal dopamine, and seizure activity. If sepsis is present, brain damage is also enhanced by the release of lipopolysaccharide, interleukin-1 β , and tumor necrosis factor α .¹⁶

The cardiovascular manifestations of respiratory alkalosis differ in passive and active hyperventilation. The induction of acute hypocapnia in anesthetized subjects (i.e., passive hyperventilation) results in a decrease in cardiac output, an increase in peripheral resistance, and a decrease in the systemic blood pressure. By contrast, active hyperventilation does not change or might even increase cardiac output and leaves systemic blood pressure virtually unchanged. The discrepant response of cardiac output during hyperventilation probably reflects the decrease in venous return caused by mechanical ventilation in passive hyperventilation and the reflex tachycardia consistently observed in active hyperventilation. Sustained hypocapnia induced by exposure to high altitude for several weeks results in a cardiac output equal to or higher than control values. Although acute hypocapnia does not lead to cardiac arrhythmias in normal volunteers, it appears that it contributes to the generation of both atrial and ventricular tachyarrhythmias in patients with ischemic heart disease; such arrhythmias are frequently resistant to standard forms of therapy. Chest pain and ischemic ST-T wave changes have been observed in acutely hyperventilating subjects with no evidence of fixed lesions on coronary angiography.

Diagnosis

Evaluation of the patient's history, physical examination, and ancillary laboratory data are required to establish the diagnosis of respiratory alkalosis.^{10,15} Careful observation can detect abnormal patterns of breathing in some patients, yet marked hypocapnia can occur without a clinically evident increase in respiratory effort. Arterial blood gas determinations are required to confirm the presence of hyperventilation.

The diagnosis of respiratory alkalosis, especially the chronic form, is frequently missed; physicians often misinterpret the electrolyte pattern of hyperchloremic hypobicarbonatemia as indicative of normal anion gap metabolic acidosis. If the patient's acid-base profile reveals hypocapnia in association with alkalemia, at least an element of respiratory alkalosis must be present. Yet hypocapnia might be associated with a normal or an acidic pH because of the concomitant presence of additional acid-base disorders. One should also note that mild degrees of chronic hypocapnia leave blood pH within the high-normal range. The diagnosis of respiratory alkalosis can have important clinical implications; it often provides a clue to the presence of an unrecognized, serious disorder or signals the gravity of a known underlying disease.

Treatment

A synopsis of the management of respiratory alkalosis is presented in Figure 14.9. The widely held view that hypocapnia

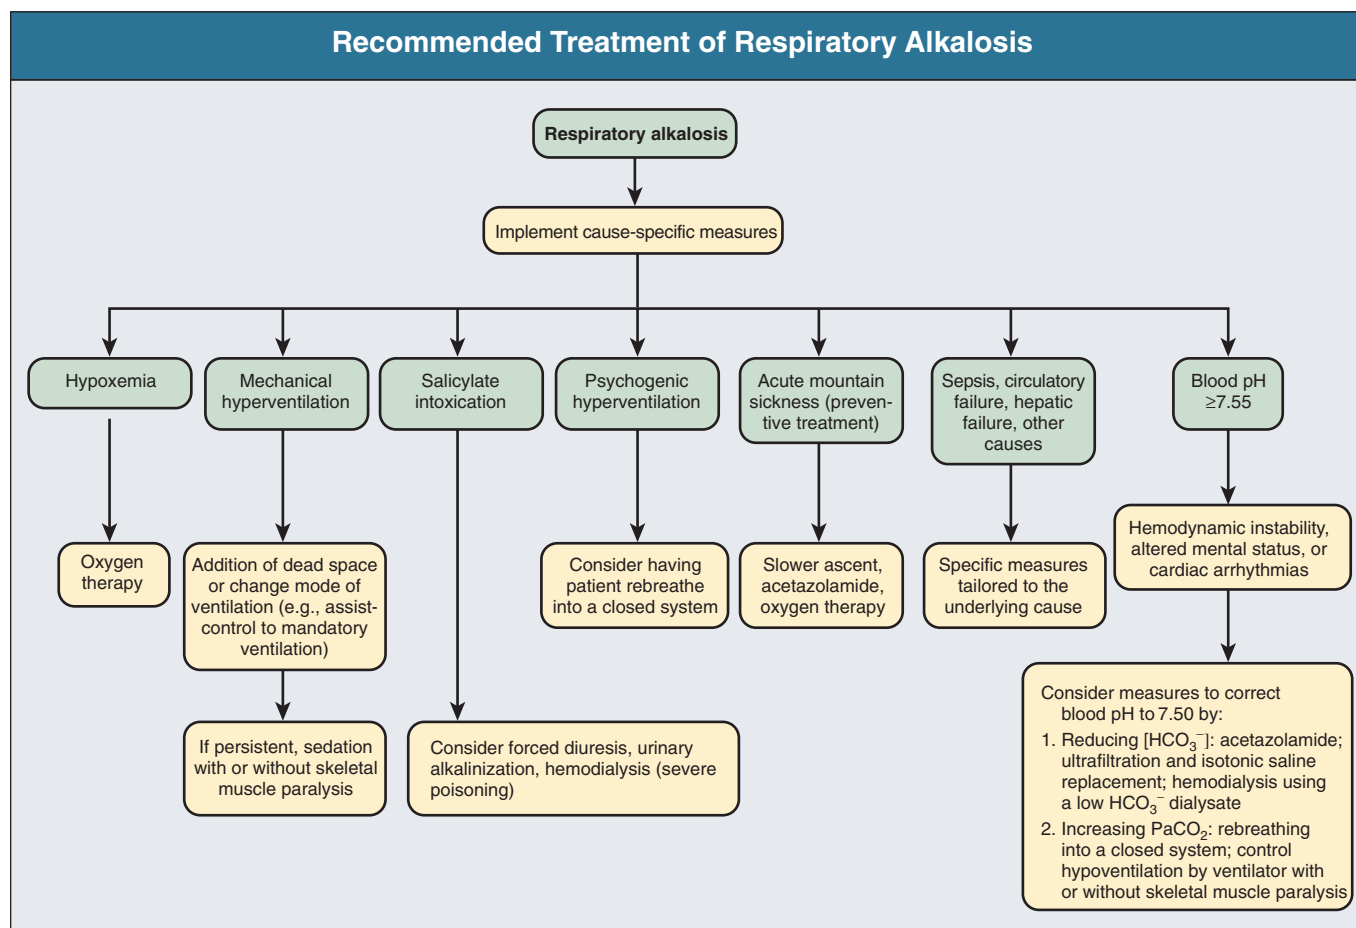

Figure 14.9 Recommended treatment of respiratory alkalosis.

poses little risk to health under most conditions is no longer considered accurate. In fact, substantial hypocapnia in hospitalized patients, whether it is spontaneous or deliberately induced, may result in transient or permanent damage in the brain as well as in the respiratory and cardiovascular systems.¹⁶ Furthermore, rapid correction of severe hypocapnia leads to vasodilation of ischemic areas, resulting in reperfusion injury in the brain and lung. Consequently, severe hypocapnia in hospitalized patients must be prevented whenever possible, and if it is present, abrupt correction should be avoided. Severe alkalemia caused by acute primary hypocapnia requires corrective measures that depend on whether serious clinical manifestations are present. Such measures can be directed at reduction of plasma bicarbonate concentration, increase of P_{aCO_2} , or both. Even if baseline plasma bicarbonate concentration is moderately decreased, reducing it further can be particularly rewarding in this setting, as this maneuver combines effectiveness with relatively little risk. For patients with the anxiety-hyperventilation syndrome, in addition to reassurance or sedation, rebreathing into a closed system (e.g., a paper bag) might prove helpful by interrupting the vicious circle that can result from the reinforcing effects of the symptoms of hypocapnia.

Respiratory alkalosis resulting from severe hypoxemia requires O_2 therapy. The oral administration of 250 to 500 mg acetazolamide twice daily can be beneficial in the management of signs and symptoms of high-altitude sickness, a syndrome characterized by hypoxemia and respiratory alkalosis.¹⁵ Of course, patients undergoing mechanical ventilation lend themselves to an effective correction of hypocapnia (whether it is caused by maladjusted ventilator or other factors) by resetting of the device.

MIXED ACID-BASE DISTURBANCES

Definition

Mixed acid-base disturbances are defined as the simultaneous presence of two or more acid-base disorders. Such association might include two or more simple acid-base disorders (e.g., metabolic acidosis and respiratory alkalosis), two or more forms of a simple disturbance having different time course or

pathogenesis (e.g., acute and chronic respiratory acidosis or high anion gap and hyperchloremic metabolic acidosis, respectively), or a combination of these two forms.¹⁷ The secondary or adaptive response to a simple acid-base disorder cannot be taken as one of the components of a mixed disorder.

Etiology and Pathogenesis

Mixed acid-base disturbances are commonly observed in hospitalized patients, especially those in critical care units.¹⁸ Characterization of these disorders and proper identification of their pathogenesis can be challenging tasks and are a prerequisite for taking sound corrective action. Certain clinical settings are commonly associated with mixed acid-base disorders, including cardiorespiratory arrest, sepsis, drug intoxications, diabetes mellitus, and organ failure (especially renal, hepatic, and pulmonary failure). Patients with severe renal impairment or end-stage renal disease (ESRD) are prone to mixed acid-base disturbances of great complexity and severity.¹⁹ Metabolic acidosis of the high anion gap type is frequently accompanied by a component of hyperchloremic acidosis, inability to mount an appropriate secondary response to chronic respiratory acidosis or alkalosis, inability to respond to a load of fixed acids (e.g., lactic acid) or a primary loss of alkali (e.g., diarrhea) with the expected increase in net acid excretion, and inability to respond to an alkali load with bicarbonaturia despite the presence of an increased plasma HCO_3^- concentration. As a result, these patients are particularly vulnerable to the development of both extreme acidemia and extreme alkalemia.

A practical classification of mixed acid-base disorders recognizes three main groups of disturbances in accordance with the preceding definition (Fig. 14.10). Representative examples are depicted in Figure 14.11, and some of these mixed disorders are reviewed.

Metabolic Acidosis and Respiratory Acidosis

The expected hypocapnia secondary to metabolic acidosis is estimated by $\Delta P_{aCO_2}/\Delta[HCO_3^-]$ equal to 1.2 mm Hg/mEq/L; if measured P_{aCO_2} exceeds 5 mm Hg the estimated value, respiratory acidosis is also present. Clinical examples of metabolic

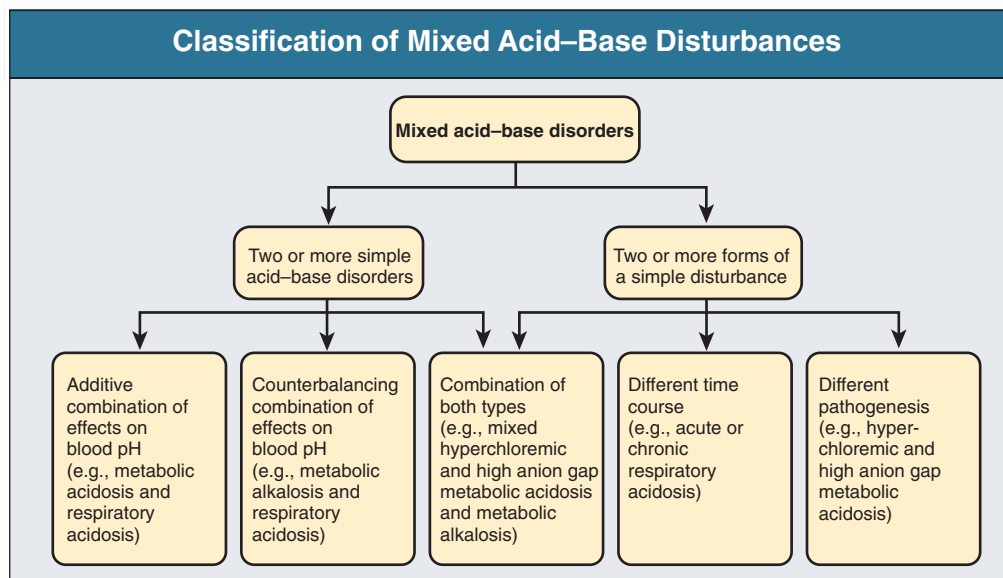

Figure 14.10 Classification of mixed acid-base disturbances.

Representative Examples of Mixed Acid-Base Disorders									
Type of Mixed Disorder	Example No.	pH	Paco ₂ (mm Hg)	HCO ₃ ⁻ (mmol/l)	Na ⁺ (mmol/l)	K ⁺ (mmol/l)	Cl ⁻ (mmol/l)	Anion gap (mmol/l)	Clinical Circumstances
Hyperchloremic and high anion gap metabolic acidosis	1	7.12	16	5	137	3.6	114	18	Diabetic ketoacidosis with adequate salt and water balance
Mixed high anion gap metabolic acidosis and metabolic alkalosis	2	7.36	31	17	132	4.0	89	26	Alcoholic liver disease, vomiting, and lactic acidosis
	3	7.40	40	24	143	5.5	95	24	Diabetic ketoacidosis and lactic acidosis after bicarbonate therapy
Mixed high anion gap metabolic acidosis and respiratory acidosis	4	7.18	44	16	133	5.7	100	17	Hepatic, renal, and pulmonary failure
Metabolic alkalosis and respiratory acidosis	5	7.44	55	36	135	3.8	84	15	Chronic obstructive pulmonary disease (COPD) and diuretics
Metabolic alkalosis and respiratory alkalosis	6	7.60	40	38	131	3.6	77	16	Congestive heart failure and diuretics
Acute or chronic respiratory acidosis	7	7.22	80	32	141	4.3	99	10	Chronic obstructive pulmonary disease (COPD) and therapy with O ₂ -rich mixtures

Figure 14.11 Representative examples of mixed acid-base disorders. Anion gap is calculated as $[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$.

acidosis combined with respiratory acidosis include untreated cardiopulmonary arrest, circulatory failure in patients with COPD, severe renal failure associated with hypercapnic respiratory failure, various intoxications, and hypokalemic (or less frequently hyperkalemic) paralysis of respiratory muscles in patients with diarrhea or renal tubular acidosis (Fig. 14.12; see also Fig. 14.11, example 4).

Metabolic Alkalosis and Respiratory Alkalosis

Metabolic alkalosis combined with respiratory alkalosis might be encountered in patients with primary hypocapnia associated with chronic liver disease who develop metabolic alkalosis from a variety of causes, including vomiting, nasogastric drainage, diuretics, profound hypokalemia, and alkali administration (e.g., absorption of antacids; infusion of lactated Ringer's solution, alimentation solutions, or citrated blood products), especially in the context of renal impairment. It also occurs in critically ill patients, particularly those undergoing mechanical ventilation, and in patients with respiratory alkalosis, caused by either pregnancy or heart failure, who experience metabolic alkalosis attributable to diuretics or vomiting (Fig. 14.13; see also Fig. 14.11, example 6).

Metabolic Alkalosis and Respiratory Acidosis

Metabolic alkalosis and respiratory acidosis is one of the most frequently encountered mixed acid-base disorders. The usual clinical setting involves COPD in conjunction with diuretic therapy, but it can occur with other causes of metabolic alkalosis (e.g., vomiting, administration of corticosteroids) (Fig. 14.14; see also Fig. 14.11, example 5). Critically ill patients with respiratory failure caused by acute respiratory distress syndrome and occasionally those with profound hypokalemia with diaphragmatic muscle weakness also might develop this mixed disorder.

Metabolic Acidosis and Respiratory Alkalosis

The combination of metabolic acidosis and respiratory alkalosis, like respiratory acidosis and metabolic alkalosis, is characterized

by normal or nearly normal blood pH; its two components exert offsetting effects on systemic acidity (Fig. 14.15). This disorder is common in intensive care units and is generally associated with high mortality. Causes of the primary hypocapnia include fever, hypotension, gram-negative septicemia, pulmonary edema, hypoxemia, and mechanical hyperventilation. The component of metabolic acidosis, in turn, might be lactic acidosis (e.g., complicating shock, hepatic failure) or renal acidosis. Salicylate intoxication is another cause of this mixed acid-base disorder. Stimulation of the ventilatory center in the brainstem accounts for the respiratory alkalosis, whereas the accelerated production of organic acids (including pyruvic, lactic, and keto acids) and, to a small extent, the accumulation of salicylic acid itself are responsible for the metabolic acidosis.

Metabolic Acidosis and Metabolic Alkalosis

Metabolic acidosis and metabolic alkalosis are typically observed in patients with alcoholic liver disease who develop fasting ketoacidosis or lactic acidosis in conjunction with metabolic alkalosis caused by vomiting, diuretics, or other causes (see Fig. 14.11, examples 2 and 3). Protracted vomiting or nasogastric suction superimposed on uremic acidosis, diabetic ketoacidosis, or metabolic acidosis caused by diarrhea might also generate this offsetting metabolic combination. A similar picture might develop after administration of alkali during cardiopulmonary resuscitation or as therapy for diabetic ketoacidosis.

Mixed Metabolic Acidosis

Mixed high anion gap metabolic acidosis in patients with diabetic or alcoholic ketoacidosis may be combined with lactic acidosis resulting from circulatory failure. Uremic patients with associated lactic acidosis or ketoacidosis are another example of mixed high anion gap acidosis. Mixed hyperchloremic metabolic acidosis is seen in patients with renal tubular acidosis or those being treated with carbonic anhydrase inhibitors who also suffer substantial fecal losses of HCO₃⁻ caused by severe diarrhea. Coexistence of hyperchloremic and high anion gap metabolic acidosis

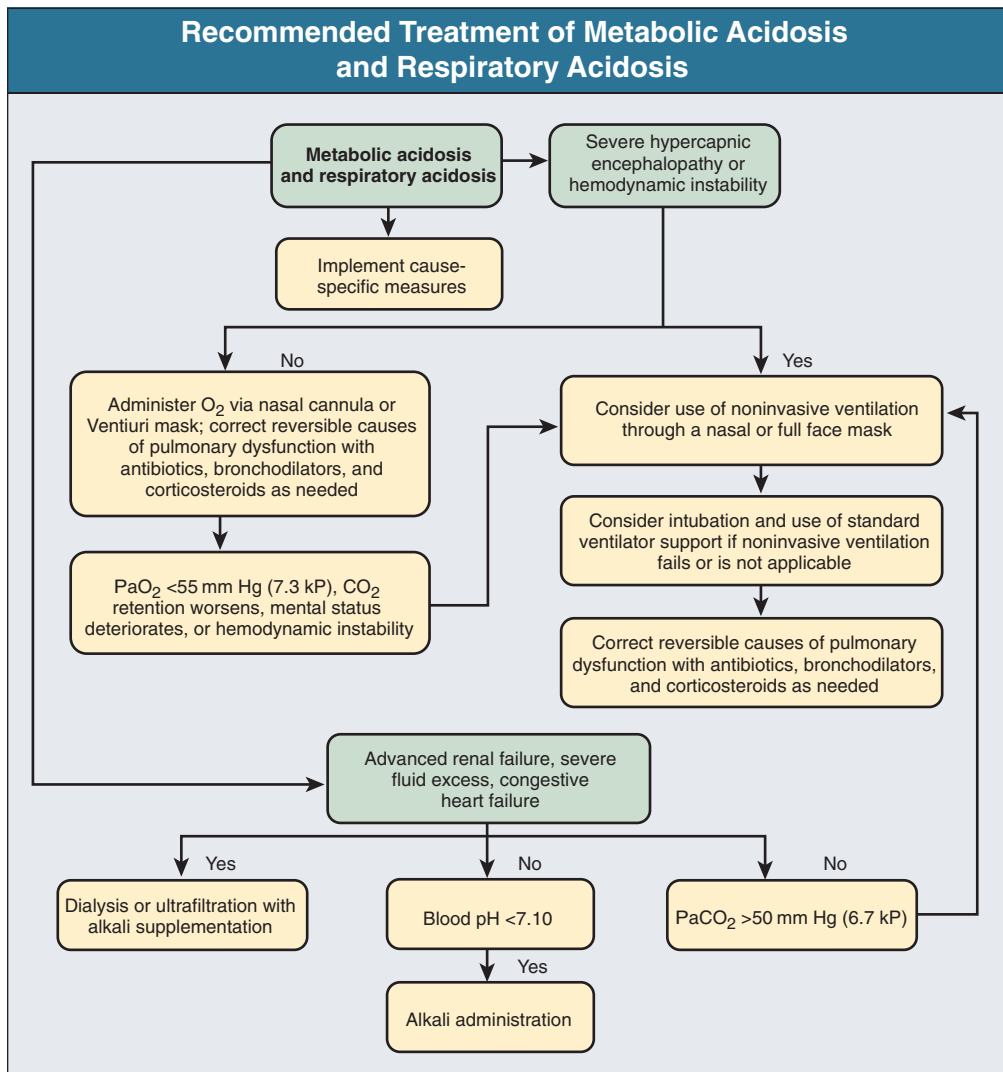

Figure 14.12 Recommended treatment of metabolic acidosis and respiratory acidosis.

occurs in patients with profuse diarrhea whose circulation becomes sufficiently compromised to generate, in turn, a high anion gap metabolic acidosis (as a result of renal failure or lactic acidosis). Patients with diabetic ketoacidosis, whose renal function is maintained at reasonable levels by adequate salt and water intake, might develop an element of hyperchloremic metabolic acidosis because of preferential excretion of ketone anions and conservation of Cl^- (see Fig. 14.11, example 1).²⁰

Mixed Metabolic Alkalosis

The coincidence of several processes that each contribute to a primary increase in plasma HCO_3^- (including diuretic therapy, vomiting, mineralocorticoid excess, and severe potassium depletion) will give rise to mixed metabolic alkalosis.

Triple Disorders

The most frequent triple disorders comprise two cardinal metabolic disturbances in conjunction with either respiratory acidosis or respiratory alkalosis, for example, severely ill patients with COPD and CO_2 retention who simultaneously develop metabolic alkalosis (usually caused by diuretics and a Cl^- -restricted diet) and metabolic acidosis (commonly lactic acidosis caused by

hypoxemia, hypotension, or sepsis). This type of triple disorder also might be encountered during cardiopulmonary resuscitation when an element of metabolic alkalosis caused by alkali administration is superimposed on preexisting respiratory acidosis and metabolic (lactic) acidosis. Patients with respiratory alkalosis caused by advanced congestive heart failure also might have diuretic-induced metabolic alkalosis and lactic acidosis from tissue hypoperfusion. Such triple acid-base disorders can also be seen in patients with chronic alcoholism who develop metabolic alkalosis from vomiting, lactic acidosis from volume depletion or ethanol intoxication, and respiratory alkalosis from hepatic encephalopathy or sepsis.

Less common are triple disorders encompassing two cardinal respiratory disturbances in combination with either metabolic acidosis or metabolic alkalosis. The typical presentation involves critically ill patients with chronic respiratory acidosis who experience an abrupt reduction in PaCO_2 because of mechanical ventilation and superimposed metabolic acidosis (usually lactic acidosis, reflecting circulatory failure) or metabolic alkalosis (e.g., as a result of gastric fluid loss, diuretics). In the last circumstance, extreme alkalemia might ensue because of the concomitant presence of hypocapnia and hyperbicarbonatemia. Even more

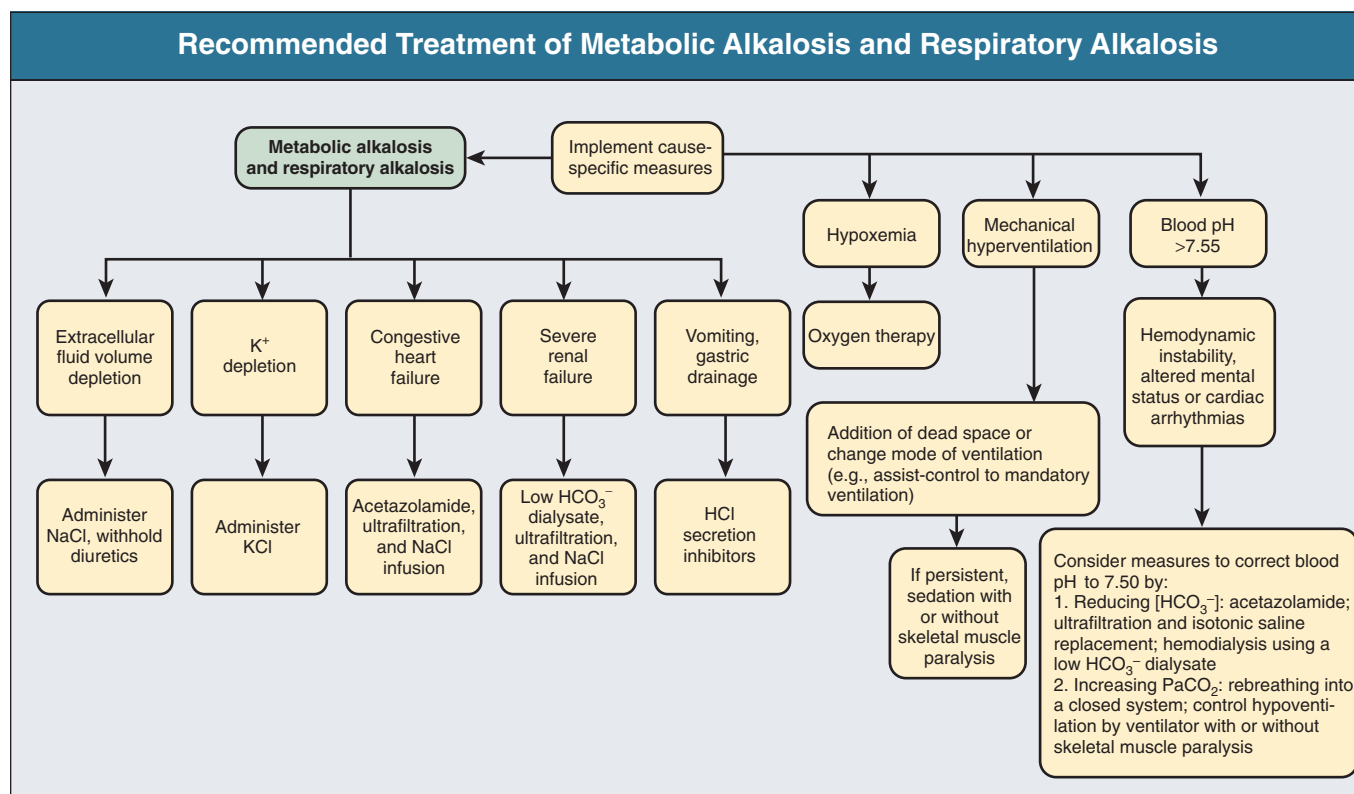

Figure 14.13 Recommended treatment of metabolic alkalosis and respiratory alkalosis.

infrequently, this same clinical setting might give rise to a quadruple acid-base disorder in which all four cardinal acid-base disturbances coexist.

Clinical Manifestations

The symptoms and signs of the underlying disease that give rise to the observed mixed acid-base disorder dominate the clinical picture, but the development of severe abnormalities in either PaCO_2 (severe hypocapnia or hypercapnia) or systemic acidity (profound acidemia or alkalemia) might be responsible for the superimposition of additional clinical manifestations. On the one hand, profound hypocapnia might induce obtundation, generalized seizures, and occasionally even coma or death as a result of a critical reduction in cerebral blood flow and other mechanisms. Rarely, angina pectoris also might occur. On the other hand, severe hypercapnia might generate a profound encephalopathy with the classic features of pseudotumor cerebri, including headaches, obtundation, vomiting, and bilateral papilledema caused by increased intracranial pressure. Extreme acidemia results in depression of the central nervous system as well as the cardiovascular system.⁷ Reduction in myocardial contractility and peripheral vascular resistance triggered by acidemia might result in severe hypotension. Finally, profound alkalemia might elicit paresthesias, tetany, cardiac dysrhythmias, or generalized seizures.

Diagnosis

The basic principles underlying the diagnosis of mixed acid-base disorders are identical to those required for the identification of

simple acid-base disturbances. These include assessment of the accuracy of the acid-base data by ensuring that the available values for pH, PaCO_2 , and plasma bicarbonate concentration satisfy the mathematical constraints of the Henderson-Hasselbalch equation; obtainment of a careful history and performance of a complete physical examination; analysis of the plasma anion gap and other ancillary laboratory data; and knowledge of the quantitative aspects of the adaptive response to each of the four simple acid-base disturbances. Adherence to these principles cannot be overemphasized. Even experienced clinicians risk misdiagnosis of the prevailing acid-base status by bypassing this systematic approach.

Normality of the acid-base parameters is not in itself sufficient for diagnosis of normal acid-base status; indeed, normal acid-base values might be the fortuitous result of mixed acid-base disorders (e.g., high anion gap acidosis treated with alkali infusion, diarrhea-induced metabolic acidosis in conjunction with vomiting-induced metabolic alkalosis). A given set of acid-base parameters is never diagnostic of a particular acid-base disorder, whether it is simple or mixed in nature; rather, it is consistent with a range of acid-base abnormalities. What on the surface appears to be a clear-cut simple acid-base disorder might actually reflect the interplay of a number of coexisting acid-base disturbances. Information from the patient's history and findings from the physical examination frequently provide important insights into the prevailing acid-base status as well as useful clues to the differential diagnosis.

A critical component of the diagnostic process is the examination of the plasma anion gap (Fig. 14.16). This derived parameter provides important insights into the nature of the prevailing changes in plasma HCO_3^- concentration. An elevated plasma

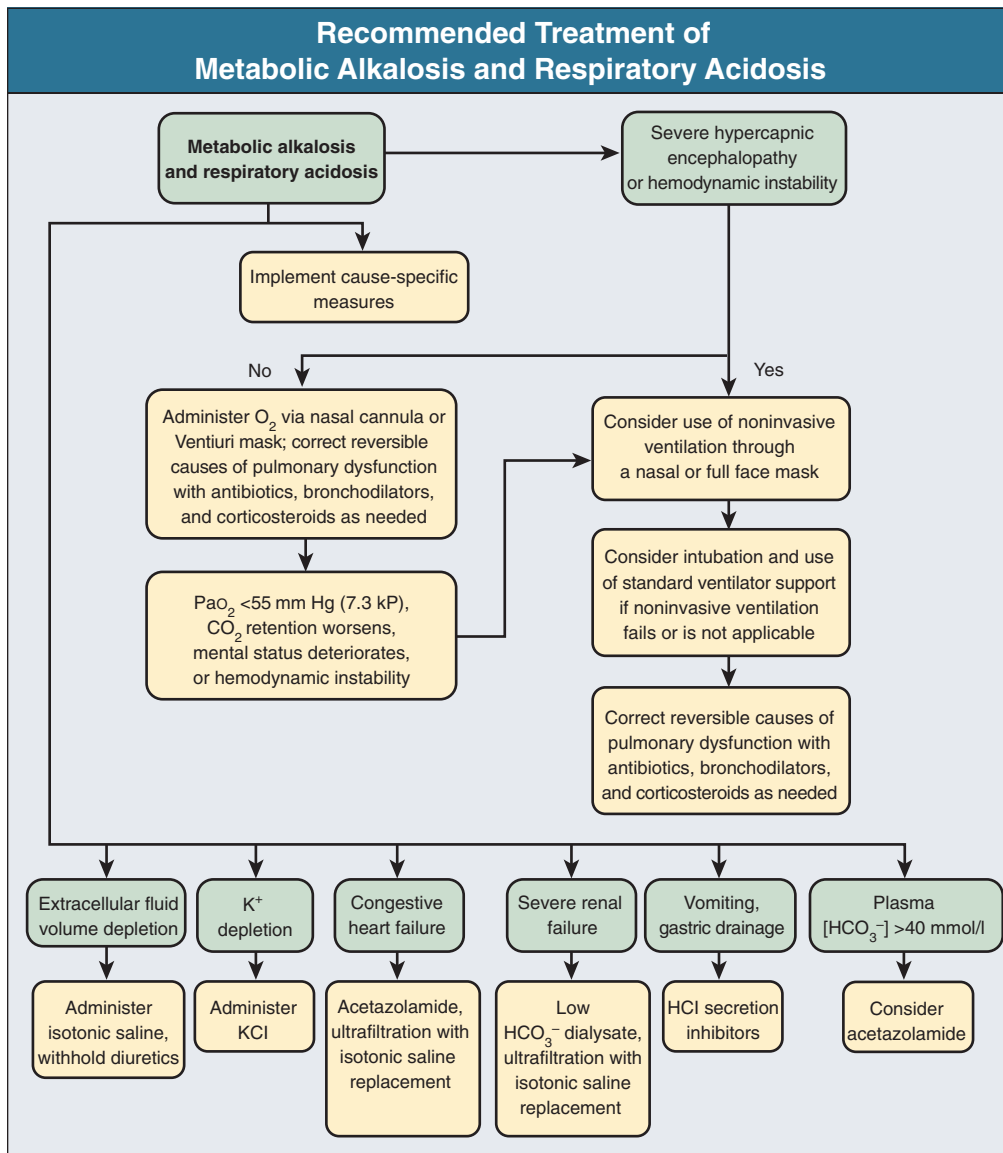

Figure 14.14 Recommended treatment of metabolic alkalosis and respiratory acidosis.

anion gap might offer the first clue to the presence of disordered acid-base status despite normal acid-base parameters. In the presence of a plasma HCO_3^- deficit ($\Delta[\text{HCO}_3^-]_p$), a normal or subnormal value for the plasma anion gap denotes that the entire decrease in HCO_3^- can be attributed to acidifying processes resulting in the loss of alkali (e.g., diarrhea, renal tubular acidosis) or to respiratory alkalosis. By comparison, with a high anion gap metabolic acidosis, there is usually a close reciprocal stoichiometry between the decrease in serum HCO_3^- and the increase in the anion gap, termed the $\Delta(\text{anion gap})$. A reduction in serum HCO_3^- of 10 mmol/l is associated, therefore, with a $\Delta(\text{anion gap})$ of 10 mmol/l. Addition of the value for the $\Delta(\text{anion gap})$ to the prevailing level of serum HCO_3^- allows the derivation of the basal value of HCO_3^- existing before the development of the high anion gap metabolic acidosis. Appreciation of this reciprocal relationship between the $\Delta[\text{HCO}_3^-]_p$ and the $\Delta(\text{anion gap})$ is important in distinguishing between a pure high anion gap metabolic acidosis and a mixed high and normal anion gap metabolic acidosis and in detecting a mixed high anion gap metabolic acidosis and metabolic alkalosis. Additional diagnostic insights are

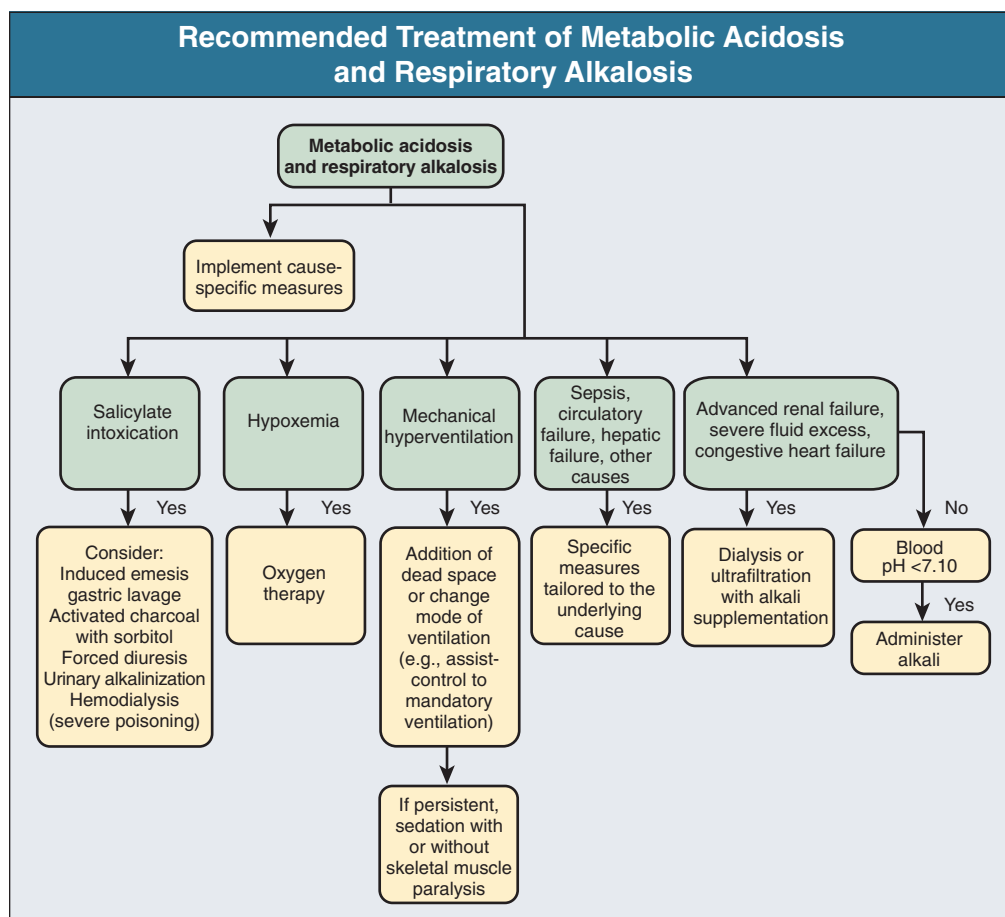

often obtained by examination of other laboratory data, including the serum potassium, glucose, urea nitrogen, and creatinine concentrations; semiquantitative measures for ketonemia or ketonuria; screening of blood or urine for toxins; and estimation of the serum osmolar gap.

Mild acid-base disorders pose particular diagnostic difficulty because of the overlap of values for the simple disturbances near the normal range. In such circumstances, any of several simple disorders or a variety of mixed disturbances might fully account for the acid-base data under evaluation. Again, careful correlation of all available clinical information should guide the diagnostic process.

Treatment

The management of mixed acid-base disturbances is aimed at restoration of the altered acid-base status by treatment of each simple acid-base disorder involved.^{1,2,17,21} Recommendations for treatment of some common mixed acid-base disturbances are presented in Figures 14.12 to 14.15.

Figure 14.15 Recommended treatment of metabolic acidosis and respiratory alkalosis.

Blood Parameters in Diagnosis of Mixed Metabolic Acid-Base Disorders

Blood Composition	Normal	High Anion Gap Acidosis	High Anion Gap and Normal Anion Gap Acidosis	Metabolic Alkalosis	High Anion Gap Acidosis and Metabolic Alkalosis
pH	7.40	7.29	7.10	7.50	7.38
PaCO ₂ (mm Hg)	40	30	20	45	35
Bicarbonate (mmol/l)	24	14	6	34	20
Anion gap (mmol/l)	10	20	20	12	26
Δ Bicarbonate	0	−10	−18	+10	−4
Δ Anion gap	0	+10	+10	+2	+16

Given the variable response time to therapy of the individual components, it is crucial to be aware of the effect that graded correction might have on systemic acidity. The asynchronous reversal of the individual components might be used at times to therapeutic advantage; on other occasions, such a practice might prove catastrophic. For example, extreme acidemia caused by metabolic acidosis and respiratory acidosis or extreme alkalemia caused by metabolic alkalosis and respiratory alkalosis might be safely corrected by a rapid return of P_{aCO_2} toward normal. By comparison, an asynchronous return of P_{aCO_2} to normal in a patient with profound metabolic acidosis and superimposed respiratory alkalosis might prove disastrous. Similarly, extreme caution should be exercised in treating patients with respiratory

acidosis and metabolic alkalosis, one of the most commonly encountered mixed acid-base disorders. Although therapeutic measures intended to improve alveolar ventilation should be instituted, an abrupt decrease in P_{aCO_2} risks development of severe alkalemia. Therefore, aggressive measures should be taken to treat metabolic alkalosis, making certain that reversal of the metabolic component does not lag behind treatment of the respiratory element. In fact, because the ventilatory drive in patients with chronic respiratory acidosis depends in part on the prevailing acidemia, reversal of a complicating element of metabolic alkalosis regularly results in improved alveolar ventilation, and consequently a decrease in P_{aCO_2} and an increase in P_{aO_2} are achieved.

Introduction to Glomerular Disease: Clinical Presentations

Jürgen Floege, John Feehally

DEFINITION

Glomerular disease has clinical presentations that vary from the asymptomatic individual who is found to have hypertension, edema, hematuria, or proteinuria at a routine medical assessment to a patient with a fulminant illness with acute kidney injury (AKI) possibly associated with life-threatening extrarenal disease (Fig. 15.1). The most dramatic symptomatic presentations are uncommon. Asymptomatic urine abnormalities are much more common but less specific; they may also indicate a wide range of nonglomerular urinary tract disease.

CLINICAL EVALUATION OF GLOMERULAR DISEASE

The history, physical examination, and investigations are aimed at excluding nonglomerular disease, finding evidence of associated multisystem disease, and establishing renal function.

History

The majority of glomerular diseases do not lead to symptoms that patients will report. However, specific questioning may reveal edema, hypertension, foamy urine, or urinary abnormalities during prior routine testing (e.g., during routine medical examinations). Multisystem diseases associated with glomerular disease include diabetes, hypertension, amyloid, lupus, and vasculitis. Apart from the individual history suggestive of these diseases, a positive family history may also be obtained in some cases. Other causes of familial renal disease may include Alport's syndrome (especially if it is associated with hearing loss; see Chapter 46), uncommon familial forms of IgA nephropathy (see Chapter 22), focal segmental glomerulosclerosis (FSGS; see Chapters 18 and 19), hemolytic-uremic syndrome (HUS; see Chapter 28), and other rare conditions (see Chapter 27). Morbid obesity can be associated with FSGS. Certain drugs and toxins may cause glomerular disease; these include minimal change disease (MCD; nonsteroidal anti-inflammatory agents [NSAIDs] and interferon), membranous nephropathy (penicillamine; NSAIDs; mercury, for example, in skin-lightening creams), FSGS (pamidronate, heroin), and HUS (cyclosporine, tacrolimus, mitomycin C, oral contraceptives). Recent or persistent infection (especially streptococcal infection, infective endocarditis, and certain viral infections; see Chapters 21, 55, and 56) may also be associated with a variety of glomerular diseases.

Various malignant neoplasms are associated with glomerular disease. These include lung, breast, and gastrointestinal carcinoma (membranous nephropathy); Hodgkin's disease (MCD);

non-Hodgkin's lymphoma (membranoproliferative glomerulonephritis [MPGN]); and renal carcinoma (amyloid; see Chapter 26). Patients will occasionally present with the renal disease as the first manifestation of a tumor.

Physical Examination

The presence of dependent pitting edema suggests the nephrotic syndrome, heart failure, or cirrhosis. In the nephrotic subject, edema is often periorbital in the morning (Fig. 15.2), whereas the face is not affected overnight in edema associated with heart failure (because of orthopnea resulting from pulmonary congestion) or cirrhosis (because the patient cannot lie flat owing to pressure on the diaphragm from ascites). As it progresses, edema of genitals and abdominal wall becomes apparent, and accumulation of fluid in body spaces leads to ascites and pleural effusions. Edema is unpleasant; it leads to feelings of tightness in the limbs and a bloated abdomen. There are practical problems of clothes and shoes no longer fitting. Yet surprisingly, edema may become massive in nephrotic syndrome before patients seek medical help; fluid gains of 20% of normal body weight are by no means unusual (Fig. 15.3). The edema becomes firm and stops pitting only when it is long-standing. In children, fluid retention may also be striking with nephritic syndrome. A useful clinical sign to help distinguish nephrotic from nephritic syndrome is Heyman's sign, the paper-thin, floppy ears typical of nephrotic syndrome. Chronic hypoalbuminemia is also associated with loss of normal pink color under the nails, resulting in white nails or white bands if the nephrotic syndrome is transient (Muehrcke's bands, Fig. 15.4). Xanthelasmas may also be present as a result of the hyperlipidemia associated with the nephrotic syndrome (Fig. 15.5).

The presence of pulmonary signs should suggest one of the pulmonary-renal syndromes (see Figs. 23.9 and 23.10). Palpable purpura may be seen in vasculitis, systemic lupus, cryoglobulinemia, or endocarditis.

Laboratory Studies

Assessment of renal function and careful examination of the urine (see Chapters 3 and 4) are critical. The quantity of urine protein and the presence or absence of dysmorphic red cells and casts will help classify the clinical presentation (see Fig. 15.1).

Certain serologic tests are also helpful. These include anti-nuclear and anti-DNA antibodies (lupus), cryoglobulins and rheumatoid factor (both suggestive of cryoglobulinemia), anti-glomerular basement membrane (anti-GBM) antibodies (Goodpasture's disease), antineutrophil cytoplasmic (ANCA) antibodies; vasculitis, and antistreptolysin O titer or streptozyme test (poststreptococcal glomerulonephritis [GN]). Serum and

Figure 15.5 Xanthelasmas in nephrotic syndrome. These prominent xanthelasmas developed within a period of 2 months in a patient with recent onset of severe nephrotic syndrome and serum cholesterol level of 550 mg/dl (14.2 mmol/l).

urine electrophoresis will detect monoclonal light chains or heavy chains (myeloma-associated amyloid or light-chain deposition disease).

Testing for the presence of ongoing bacterial or viral infections is also useful. This includes blood cultures and testing for hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) infection.

Measurement of systemic complement pathway activation by testing for serum C3, C4, and CH50 (50% hemolyzing dose of complement) is particularly helpful in limiting the differential diagnosis (Fig. 15.6).

Hypocomplementemia in Glomerular Disease			
Pathway Affected	Complement Changes	Glomerular Diseases	Nonglomerular Diseases
Classical pathway activation	C3 ↓, C4 ↓, CH50 ↓ + C4 nephritic factor	Lupus nephritis (especially class IV), mixed essential cryoglobulinemia Membranoproliferative GN type 1	
Alternative pathway activation	C3 ↓, C4 normal, CH50 ↓ + C3 nephritic factor	Poststreptococcal GN GN associated with other infection* Endocarditis, shunt nephritis, hepatitis B Hemolytic-uremic syndrome Membranoproliferative GN type II (Dense Deposit Disease)	Atheroembolic renal disease
Reduced complement synthesis	Acquired Hereditary C2 deficiency Factor H deficiency	Lupus nephritis Familial hemolytic-uremic syndrome Membranoproliferative GN type II	Hepatic disease Malnutrition

Figure 15.6 Hypocomplementemia in glomerular disease. *Glomerulonephritis (GN) with visceral abscesses is generally associated with normal or increased complement (elevations occur because complement components are acute-phase reactants). CH50, 50% hemolyzing dose of complement.

The emerging role for genetic evaluation in patients with FSGS is discussed in Chapter 19.

Imaging

Ultrasound scanning is recommended in the workup to ensure the presence of two kidneys, to rule out obstruction or anatomic abnormalities, and to assess kidney size. Renal size is often normal in GN, although large kidneys (>14 cm) are sometimes seen in nephrotic syndrome as associated with diabetes, amyloid, or HIV infection. Large kidneys can also occasionally be seen with any acute severe GN. The occurrence of small kidneys (<9 cm) suggests chronic renal disease and should limit enthusiasm for renal biopsy or aggressive immunosuppressive therapies.

Renal Biopsy

Renal biopsy is generally required to establish the type of glomerular disease and to guide treatment decisions. The principles and practice of renal biopsy are discussed in Chapter 6. There are some situations, however, in which renal biopsy is not performed. If there are no unusual clinical features in nephrotic children, the probability of MCD is so high that corticosteroids can be initiated without biopsy (see Chapter 17). In acute nephritic syndrome, if all features point to poststreptococcal GN, especially in an epidemic, biopsy can be reserved for the minority who do not show early spontaneous improvement (see Chapter 55). In anti-GBM disease (see Chapter 23), the presence of lung hemorrhage and rapidly progressive renal failure with urinary red cell casts and high titers of circulating anti-GBM antibody establishes the diagnosis without the need for a biopsy, although a biopsy may still provide prognostic information. In patients with systemic features of vasculitis, a positive ANCA titer, negative blood cultures, and a tissue biopsy specimen from another site showing vasculitis are sufficient to secure a diagnosis of renal vasculitis. Again, however, renal biopsy may provide important clues to disease activity and chronicity. Biopsy is also not generally performed in long-standing diabetes with characteristic findings suggestive of diabetic nephropathy and other evidence of microvascular complications of diabetes (see Chapter

29). Biopsy may also not be indicated in many patients with mild glomerular disease presenting with asymptomatic urine abnormalities as the prognosis is excellent and histologic findings will not alter management.

ASYMPTOMATIC URINE ABNORMALITIES

Urine testing that detects proteinuria or microscopic hematuria is often the first evidence of glomerular disease. The random nature of urine testing in most communities inevitably means that much mild glomerular disease remains undetected. In some countries, symptomless individuals may have a urine test only if they require medical approval for some key life event: to obtain life insurance, to join the armed forces, or sometimes for employment purposes. In other countries, for example, Japan, urinalysis is performed routinely in school or for employment. These different practices may partly account for the apparently variable incidence of certain diseases, such as IgA nephropathy. Asymptomatic proteinuria and hematuria, and the combination of the two, increase in prevalence with age (Fig. 15.7).¹ Nevertheless, there is no evidence to justify routine population-wide screening for asymptomatic urine abnormalities as renal biopsy and therapeutic intervention are rarely required when renal function is preserved. Screening, in particular for microalbuminuria, may be indicated for high-risk populations, for example, patients with diabetes, hypertension, or cardiovascular disease, and those with a family history of renal disease.

Asymptomatic Microscopic Hematuria

Microscopic hematuria is defined as the presence of more than two red blood cells per high-power field in a spun urine sediment (3000 rpm for 5 minutes) or more than 10×10^6 red blood cells/liter.

Microscopic hematuria is common in many glomerular diseases, especially IgA nephropathy and thin basement membrane nephropathy, although there are many other causes of hematuria (discussed further in Chapter 46). A glomerular origin should especially be considered if more than 5% of the red cells are acanthocytes (see Chapter 4) or if the hematuria is accompanied by red cell casts or proteinuria (Fig. 15.8).

Figure 15.7 Prevalence of asymptomatic proteinuria and hematuria with age. Mass screening of a population of 107,192 adult men **A**, and women **B**, in Okinawa, Japan. Hematuria is more common in women. (Modified from reference 1.)

Pathogenesis

Glomerular hematuria is thought to result from small breaks in the GBM that allow extravasation of red blood cells into the urinary space. This may occur in the peripheral capillary wall but more commonly occurs in the paramesangial basement membrane, particularly in diseases in which there is injury to the mesangium (mesangiolytic).

Evaluation

The evaluation of microscopic hematuria, which is discussed further in Chapter 46, begins with a thorough history. Urine culture should exclude urinary or prostatic infection. Phase contrast microscopy should follow in cases of persistent microscopic hematuria to search for dysmorphic red cells and red cell casts. Any detectable proteinuria in the setting of asymptomatic microscopic hematuria virtually excludes “urologic” bleeding and strongly suggests a glomerular origin. If this evaluation is non-diagnostic, renal imaging is performed to exclude anatomic lesions such as polycystic kidneys, stones, tumors, and arteriovenous malformations.

Figure 15.8 Red cell cast. A red cell cast typical of glomerular hematuria.

In those older than 40 years who have persistent isolated microscopic hematuria without evidence of a glomerular origin (see previous discussion), cystoscopy is mandatory to exclude uroepithelial malignant disease. In people younger than 40 years, such malignant disease is so rare that cystoscopy is not recommended. If all the prior study results are normal, a glomerular etiology is likely.² The glomerular etiology can be determined only by renal biopsy, but this is rarely done because the prognosis is excellent in the setting of normal renal function, normal blood pressure, and low-grade proteinuria (<0.5 g/day). However, repeated evaluation is mandatory.

Asymptomatic Non-nephrotic Proteinuria

The hallmark of glomerular disease is the excretion of protein in the urine. Normal urine protein excretion is less than 150 mg/24 h (consisting of 20 to 30 mg of albumin, 10 to 20 mg of low-molecular-weight proteins that undergo glomerular filtration, and 40 to 60 mg of secreted proteins such as Tamm-Horsfall protein and IgA). Proteinuria is identified and quantified by dipstick testing or by assay in timed urine collections. The interpretation of these methods is discussed in Chapter 4.

Microalbuminuria is defined as the excretion of 30 to 300 mg of albumin per day, equivalent to a urine albumin to creatinine (g/g) ratio of 0.03 to 0.3, and is detected by quantitative immunoassay or by special urine dipsticks as this is below the sensitivity of the normal dipstick. This measurement is primarily used to identify diabetic subjects at risk for development of nephropathy and to assess cardiovascular risk, for example, in patients with hypertension.

Non-nephrotic proteinuria is usually defined as a urine protein excretion of less than 3.5 g/24 h or a urine protein to creatinine (g/g) ratio of less than 3. Although nephrotic-range proteinuria is absolutely characteristic of glomerular disease, asymptomatic proteinuria (<3.5 g/24 h) is much less specific and may occur with a wide range of nonglomerular parenchymal diseases as well as with nonparenchymal renal and urinary tract conditions that must be excluded by clinical evaluation and investigation.

Increased urine protein excretion may result from alterations in glomerular permeability or tubulointerstitial disease, although

only in glomerular disease will it be in the nephrotic range. It can also occur from increased filtration through normal glomeruli (overflow proteinuria).

Overflow Proteinuria

Overflow proteinuria is typical of urinary light-chain excretion. It is seen in myeloma but can occur in other settings (such as the release of lysozyme by leukemic cells) and should be suspected when the urine dipstick is negative for albumin despite detection of large amounts of proteinuria by other tests.

Tubular Proteinuria

Tubulointerstitial disease can also be associated with low-grade (usually <2 g/day) proteinuria. In addition to the loss of tubular proteins (such as α_1 - or β_2 -microglobulin), there will also be some albuminuria due to impaired tubular reabsorption of filtered albumin. Tubular proteinuria accompanying glomerular proteinuria is an adverse prognostic sign in various glomerular diseases as it usually indicates advanced tubulointerstitial damage.

Glomerular Proteinuria

Glomerular proteinuria is further classified into that which is transient or hemodynamic (functional), that which is present only during the day (orthostatic), and that which is persistent or fixed.

Functional Proteinuria Functional proteinuria refers to the transient non-nephrotic proteinuria that can occur with fever, exercise, heart failure, and hyperadrenergic or hyperreninemic states. Functional proteinuria is benign; it is usually assumed to be hemodynamic in origin and to be the consequence of increases in single-nephron flow or pressure.

Orthostatic Proteinuria In children and young adults, low-grade glomerular proteinuria may be orthostatic, meaning that proteinuria is absent when urine is generated in the recumbent position. If there is no proteinuria in early morning urine, the diagnosis of orthostatic proteinuria can be made. The mechanism of orthostasis is not understood. Total urine protein in orthostatic proteinuria is usually less than 1 g/24 h; hematuria and hypertension are absent. Renal biopsy usually shows normal morphology or occasionally mild glomerular change. The prognosis is uniformly good, and renal biopsy is not indicated.³

Fixed Non-nephrotic Proteinuria Fixed non-nephrotic proteinuria is usually caused by glomerular disease. If glomerular filtration rate (GFR) is preserved and proteinuria is less than 1 g/day, biopsy is not indicated but prolonged follow-up is necessary so long as significant proteinuria persists to rule out the possibility of disease progression. Previous studies indicate that the biopsy findings in these patients will be similar to those seen in nephrotic syndrome, although milder lesions are more common, particularly mesangial proliferative GN without immune deposits. In general, no treatment is necessary.

Although it is controversial, many nephrologists will perform a renal biopsy in patients with normal GFR if non-nephrotic proteinuria exceeds 1 g/day, in particular if it persists after initiation of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy.

The evaluation of isolated asymptomatic proteinuria is summarized in Figure 15.9.

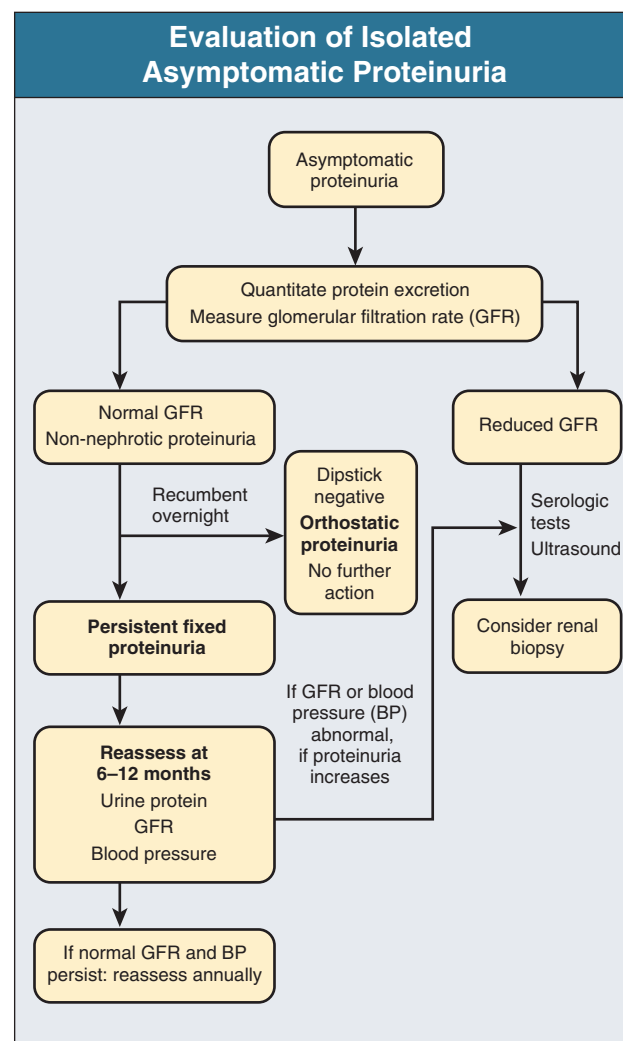

Figure 15.9 Evaluation of patients with isolated asymptomatic proteinuria.

Asymptomatic Proteinuria with Hematuria

When asymptomatic hematuria and proteinuria coincide, there is a much greater risk of significant glomerular injury, hypertension, and progressive renal dysfunction. Minor histologic changes are less common. Renal biopsy is indicated even if urine protein is only 0.5 to 1 g/24 h if there is also persistent microscopic hematuria with casts.

MACROSCOPIC HEMATURIA

Episodic painless macroscopic hematuria associated with glomerular disease is often brown or “smoky” rather than red, and clots are unusual. It must be distinguished from other causes of red or brown urine, including hemoglobinuria, myoglobinuria, porphyria, consumption of food dyes (particularly beetroot), and intake of drugs (in particular rifampin).

Macroscopic hematuria caused by glomerular disease is observed primarily in children and young adults and is rare past the age of 40 years. Most cases are caused by IgA nephropathy, but hematuria may occur with other glomerular and nonglomerular renal diseases, including acute interstitial nephritis. Although macroscopic hematuria is typically painless, there may

Common Glomerular Diseases Presenting as Nephrotic Syndrome in Adults		
Disease	Associations	Serologic Tests Helpful in Diagnosis
Minimal change disease (MCD)	Allergy, atopy, NSAIDs, Hodgkin's disease	None
Focal segmental glomerulosclerosis (FSGS)	African Americans HIV infection Heroin, pamidronate	— HIV antibody —
Membranous nephropathy (MN)	Drugs: gold, penicillamine, NSAIDs Infections: hepatitis B, C; malaria Lupus nephritis Malignancy: breast, lung, gastrointestinal tract	— Hepatitis B surface antigen, anti-hepatitis C virus antibody Anti-DNA antibody —
Membranoproliferative glomerulonephritis (MPGN) (type I)	C4 nephritic factor	C3 ↓, C4 ↓
Membranoproliferative glomerulonephritis (MPGN) (type II) (Dense deposit disease)	C3 nephritic factor	C3 ↓, C4 normal
Cryoglobulinemic membranoproliferative glomerulonephritis	Hepatitis C	Anti-hepatitis C virus antibody, rheumatoid factor, C3 ↓, C4 ↓, CH50 ↓
Amyloid	Myeloma Rheumatoid arthritis, bronchiectasis, Crohn's disease (and other chronic inflammatory conditions), familial Mediterranean fever	Serum protein electrophoresis, urine immunoelectrophoresis —
Diabetic nephropathy	Other diabetic microangiopathy	None

Figure 15.10 Common glomerular diseases presenting as nephrotic syndrome in adults. HIV, human immunodeficiency virus; NSAIDs, non-steroidal antiinflammatory drugs.

be an accompanying dull loin ache that may suggest other diagnoses, such as stone disease or loin-pain hematuria syndrome. In IgA nephropathy, the frank hematuria is usually episodic, occurring within a day of an upper respiratory infection. There is a clear distinction between this history and the 2- to 3-week latency between an upper respiratory tract infection and hematuria that is highly suggestive of postinfectious (usually post-streptococcal) GN; furthermore, in poststreptococcal disease, there will usually be other features of nephritic syndrome. Macroscopic hematuria requires urologic evaluation including cystoscopy at any age unless the history (as shown previously) is characteristic of glomerular hematuria.

NEPHROTIC SYNDROME

Definition

Nephrotic syndrome is pathognomonic of glomerular disease. It is a clinical syndrome with a characteristic pentad (see Fig. 15.1).⁴ Patients may be nephrotic with preserved renal function, but in many circumstances, progressive renal failure will become superimposed when nephrotic syndrome is prolonged.

Independent of the risk of progressive renal failure, the nephrotic syndrome has far-reaching metabolic effects that can influence the general health of the patient. Fortunately, some episodes of nephrotic syndrome are self-limited, and a few respond completely to specific treatment (e.g., corticosteroids in MCD). However, for most patients, it is a chronic condition. Not all patients with proteinuria above 3.5 g/24 h will have a full nephrotic syndrome; some have a normal serum albumin concentration and no edema. This difference presumably reflects the varied response of protein metabolism; some patients sustain an increase in albumin synthesis in response to heavy proteinuria that may even normalize serum albumin.

Etiology

The major causes of nephrotic syndrome are shown in Figure 15.10. Proteinuria in the nephrotic range in the absence of edema and hypoalbuminemia has similar etiologies. The relative frequency of the different glomerular diseases varies with age (Fig. 15.11). Although it is predominant in childhood, MCD remains common at all ages.⁵ There is an increased prevalence of FSGS in African Americans, and historical comparisons indicate that FSGS is becoming more common and MPGN less common in all adults.⁶

Hypoalbuminemia

Hypoalbuminemia is mostly a consequence of urinary losses. The liver responds by increasing albumin synthesis, but this compensatory mechanism appears to be blunted in nephrotic syndrome.⁷ The end result is that serum albumin falls further. White bands in the nails (Muehrcke's bands) are a characteristic clinical sign of hypoalbuminemia (see Fig. 15.4). The increase in protein synthesis in response to proteinuria is not discriminating; as a result, proteins that are not being lost in the urine may actually increase in concentration in plasma. This is chiefly determined by molecular weight; large molecules will not spill into the urine and will increase in the plasma; smaller proteins, although synthesized to excess, will enter the urine and be diminished in the plasma. These variations in plasma proteins are clinically important in two areas: hypercoagulability and hyperlipidemia (see later discussion).

Edema

At least two major mechanisms are involved in the formation of nephrotic edema (Fig. 15.12; see Chapter 7).⁸ In the first

Age-related Variations in Nephrotic Syndrome					
	Prevalence (%)

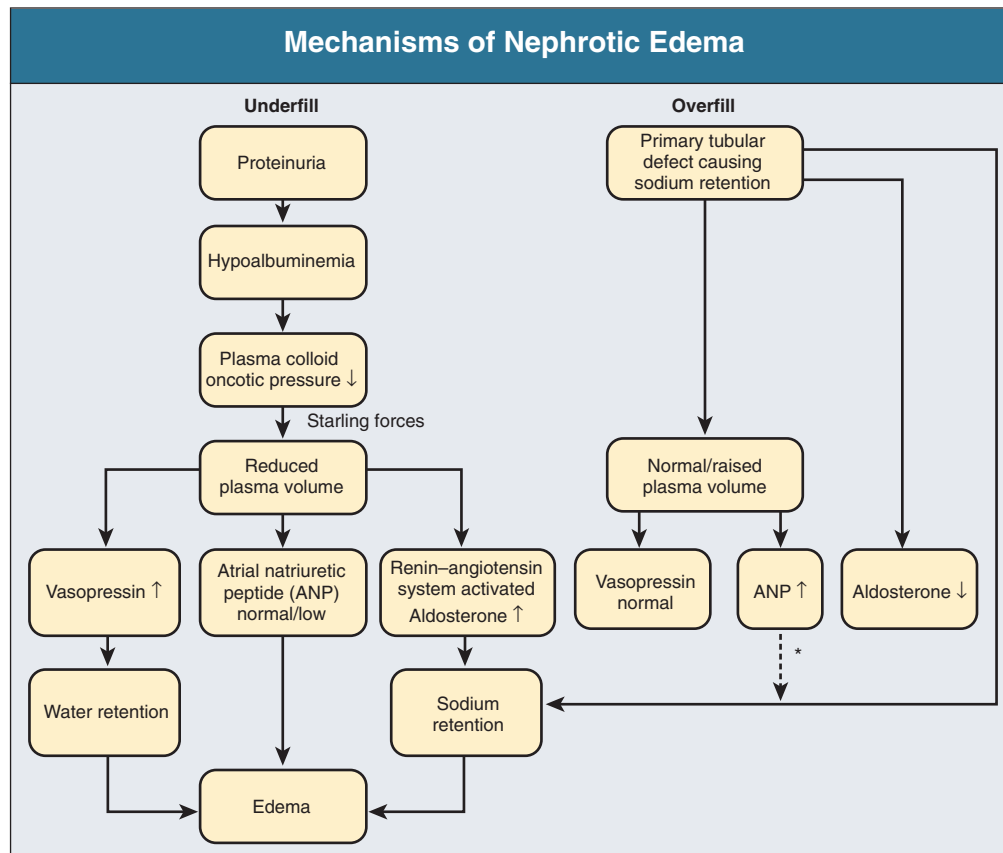

Figure 15.12 Mechanisms of nephrotic edema. *The kidney is relatively resistant to ANP in this setting, so ANP has little effect in countering sodium retention.

mechanism, which is more common in children with MCD, the edema appears to be the consequence of the low serum albumin producing a decrease in plasma oncotic pressure, which allows increased transudation of fluid from capillary beds into the extracellular space according to the laws of Starling. The consequent decrease in circulating blood volume (underfill) produces a secondary stimulation of the renin-angiotensin system, resulting in aldosterone-induced sodium retention in the distal tubule. This attempt to compensate for hypovolemia merely aggravates edema because the low oncotic pressure alters the balance of forces across the capillary wall in favor of hydrostatic pressure, forcing more fluid into the interstitial space rather than retaining it within the vascular compartment.

In many nephrotic patients, however, there appears to be a primary defect in the ability of the distal nephron to excrete sodium, possibly related to activation of the epithelial sodium channel (ENaC) by proteolytic enzymes that enter the tubular lumen in heavy proteinuria.⁹ As a result, there is an increased blood volume, the suppression of renin-angiotensin and vasopressin, and a tendency to hypertension rather than to hypotension; the kidney is also relatively resistant to the actions of atrial natriuretic peptide. An elevated blood volume results (overfill), which, in association with the low plasma oncotic pressure, provokes transudation of fluid into the extracellular space and edema. The mechanism for the defect in sodium excretion remains unknown, although it has been hypothesized that

inflammatory leukocytes in the interstitium, which are found in many glomerular diseases, may impair sodium excretion by producing angiotensin II and oxidants (the latter inactivate local nitric oxide, which is natriuretic).¹⁰

Metabolic Consequences of Nephrotic Syndrome

Negative Nitrogen Balance

The heavy proteinuria leads to marked negative nitrogen balance, usually measured in clinical practice by serum albumin. Nephrotic syndrome is a wasting illness, but the degree of muscle loss is masked by edema and not fully apparent until the patient is rendered edema free. Loss of 10% to 20% of lean body mass is not uncommon. Albumin turnover is increased in response to the tubular catabolism of filtered protein rather than merely to urinary protein loss. Increasing protein intake does not improve albumin metabolism because the hemodynamic response to an increased intake is a rise in glomerular pressure, producing enhanced urine protein losses. A low-protein diet in turn will reduce proteinuria but also reduces the albumin synthesis rate and, in the longer term, may increase the risk of a worsening negative nitrogen balance.

Hypercoagulability

Multiple proteins of the coagulation cascade have altered levels in nephrotic syndrome; in addition, platelet aggregation is enhanced.¹¹ The net effect is a hypercoagulable state that is enhanced further by immobility, coincidental infection, and hemoconcentration if the patient has a contracted plasma volume (Fig. 15.13). Not only is venous thromboembolism common at any site, but spontaneous arterial thrombosis may occur. Arterial thrombosis may occur in adults in the context of atheroma, promoting coronary and cerebrovascular events in particular; but it also occurs in nephrotic children, in whom spontaneous thrombosis of major limb arteries is an uncommon but feared

complication. Up to 10% of nephrotic adults and 2% of children will have a clinical episode of thromboembolism. Individual levels of coagulation proteins are not helpful in assessing the risk of thromboembolism, and serum albumin is mostly used as a surrogate marker. Thromboembolic events increase markedly if the serum albumin concentration decreases to less than 2 g/dl.

The hypoproteinemia and dysproteinemia produce an increase in erythrocyte sedimentation rate (ESR). Values up to 100 mm/h are not unusual, so ESR loses its clinical value as a marker of an acute-phase response in nephrotic patients.

Renal vein thrombosis (see Chapter 64) is an important complication of nephrotic syndrome. At one time, it was thought that renal vein thrombosis could cause nephrotic syndrome; this is no longer considered true. Renal vein thrombosis is reported clinically in up to 8% of nephrotic patients; but when it is sought systematically (by ultrasound or contrast venography), the frequency increases to 10% to 50%. It may be more common in membranous nephropathy than other disease patterns, although there is no explanation for this observation. Symptoms when the thrombosis is acute may include flank pain and hematuria; rarely, AKI can occur if the thrombosis is bilateral. However, the thrombosis often develops insidiously with minimal symptoms or signs because of the development of collateral blood supply. Pulmonary embolism is an important complication. Screening for renal vein thrombosis should not be routine in nephrotic patients.

Hyperlipidemia and Lipiduria

Hyperlipidemia is such a frequent finding in patients with heavy proteinuria that it is regarded as an integral feature of nephrotic syndrome.¹² Clinical stigmata of hyperlipidemia, such as xanthelasma, may have a rapid onset (see Fig. 15.5). It is not uncommon for serum cholesterol concentration to be above 500 mg/dl (13 mmol/l), although serum triglyceride levels are highly variable. The lipid profile in nephrotic syndrome (Fig. 15.14) is known to be highly atherogenic in other populations. The presumption that coronary heart disease is increased in nephrotic syndrome, owing to the combination of hypercoagulation and hyperlipidemia, has been difficult to prove. Many patients who are nephrotic for more than 5 to 10 years will develop additional cardiovascular risk factors, including hypertension and uremia, so it is difficult to separate these influences. However, it is now generally accepted that nephrotic patients do carry about a fivefold increased risk of coronary death, with the exception of those with MCD. Presumably, this is because the transience of the nephrotic state before remission with corticosteroid treatment does not subject the patient with MCD to prolonged hyperlipidemia.

There is experimental evidence that hyperlipidemia contributes to progressive renal disease by various mechanisms, with protection afforded by lipid-lowering agents. However, clinical evidence to support a role of statins in retarding chronic kidney disease progression is inconclusive¹³ as there are not yet adequate prospective clinical studies on this issue, and lipid-lowering drugs are chiefly indicated in nephrotic syndrome for cardiovascular reasons.

Several mechanisms account for the lipid abnormalities in nephrotic syndrome. These include increased hepatic synthesis of low-density lipoprotein (LDL), very low density lipoprotein (VLDL), and lipoprotein(a) secondary to the hypoalbuminemia; defective peripheral lipoprotein lipase activity resulting in increased VLDL; and urinary losses of high-density lipoprotein (HDL; see Fig. 15.14).

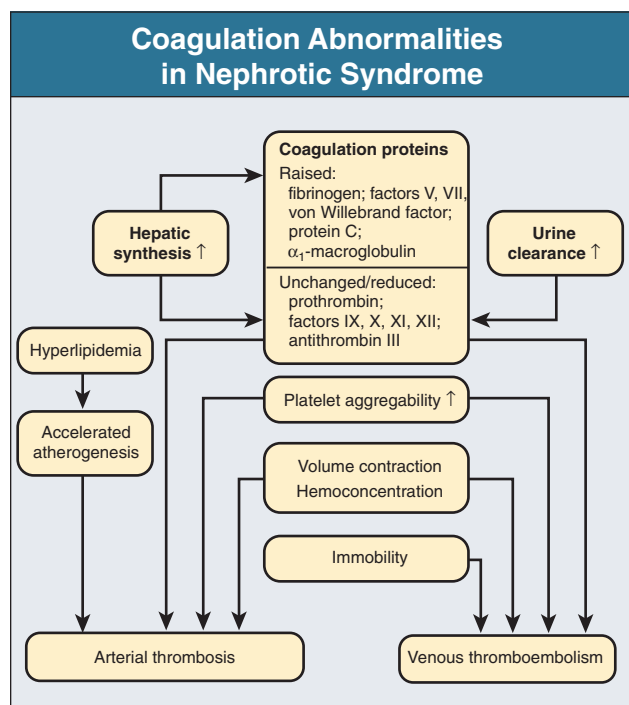

Figure 15.13 Coagulation abnormalities in nephrotic syndrome.

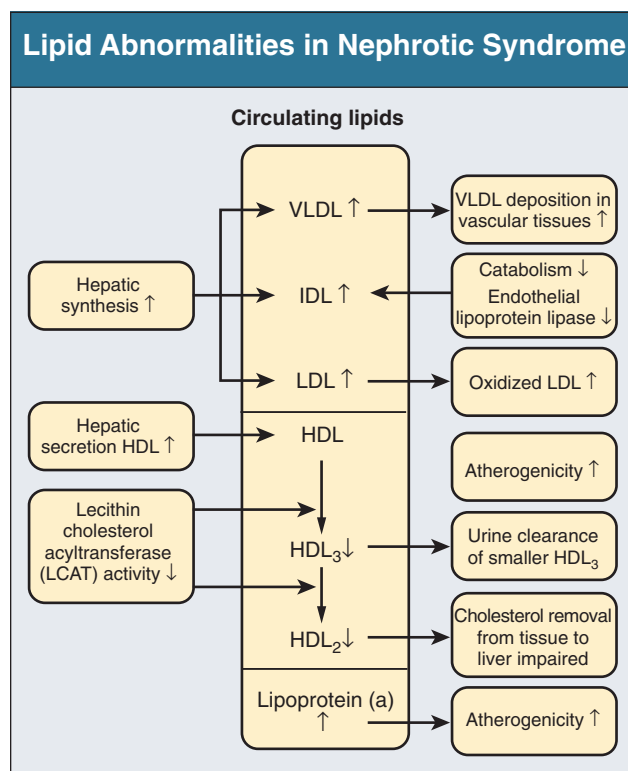

Figure 15.14 Lipid abnormalities in nephrotic syndrome. Changes in HDLs are more controversial than those in VLDLs. HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; VLDL, very low density lipoprotein.

Lipiduria, the fifth component of the nephrotic syndrome, is manifested by the presence of refractile accumulations of lipid in cellular debris and casts (oval fat bodies and fatty casts; Fig. 15.15). However, the lipiduria appears to be a consequence of the proteinuria and not of the plasma lipid abnormalities.

Other Metabolic Effects of Nephrotic Syndrome

Vitamin D-binding protein is lost in the urine, resulting in low plasma 25-hydroxyvitamin D levels, but plasma-free vitamin D is usually normal, and overt osteomalacia or uncontrolled hyperparathyroidism is very unusual in nephrotic syndrome in the absence of renal insufficiency. Thyroid-binding globulin is lost in the urine and total circulating thyroxine is reduced, but free thyroxine and thyroid-stimulating hormone are normal, and there are no clinical alterations in thyroid status. Occasional cases of copper, iron, or zinc deficiency have been described as a consequence of the loss of binding proteins in the urine.

Drug binding may be altered by the decrease in serum albumin. Although most drugs do not require dose modifications, one important exception is clofibrate, which at normal doses in nephrotic patients produces a severe myopathy. Reduced protein binding may also reduce the dose of warfarin (Coumadin) required to achieve adequate anticoagulation or the dose of furosemide required to achieve adequate fluid loss (see later discussion).

Infection

Nephrotic patients are prone to bacterial infection. Before corticosteroids were shown to be effective in childhood nephrotic syndrome, sepsis was the most common cause of death and

Figure 15.15 Fat in the urine. A hyaline cast containing oval fat bodies that are tubular epithelial cells full of fat. Oval fat bodies often appear brown.

remains a major problem in the developing world. Primary peritonitis, especially that caused by pneumococci, is particularly characteristic of nephrotic children. It is less common with increasing age; by the age of 20 years, most adults have antibodies against pneumococcal capsular antigens. Peritonitis caused by both β -hemolytic streptococci and gram-negative organisms occurs, but staphylococcal peritonitis is not reported. Cellulitis, especially in areas of severe edema, is also common, most frequently caused by β -hemolytic streptococci.

There are several explanations for the increased risk of infection. Large fluid collections are sites for bacteria to grow easily; nephrotic skin is fragile, creating sites of entry; and edema may dilute local humoral immune factors. Loss of IgG and complement factor B (of the alternative pathway) in the urine impairs host ability to eliminate encapsulated organisms such as pneumococci. Zinc and transferrin are lost in the urine, and both are required for normal lymphocyte function. Neutrophil phagocytic function is impaired in nephrotic syndrome, and a number of *in vitro* T-cell dysfunctions are described, although their clinical significance is uncertain.

Acute and Chronic Changes in Renal Function in Nephrotic Syndrome

Acute Kidney Injury

Patients with nephrotic syndrome are also at risk for the development of AKI,¹⁴ which can occur by a variety of mechanisms that are summarized in Figure 15.16. These include volume depletion or sepsis, resulting in either prerenal AKI or acute tubular necrosis¹⁵; transformation of the underlying disease (such as the development of crescentic nephritis in a patient with membranous nephropathy); development of bilateral renal vein thrombosis; increased disposition to azotemia from NSAIDs and ACE inhibitors or ARBs; and increased risk of allergic interstitial nephritis secondary to drugs, including diuretics. It has also been postulated that some patients develop AKI from intrarenal edema with compression of tubules; these patients, like nephrotic subjects with prerenal azotemia, may respond with diuresis to albumin infusions coupled with a loop diuretic.

Chronic Kidney Disease

With the exception of MCD, most causes of nephrotic syndrome are associated with some risk for the development of progressive renal failure. In this regard, one of the greatest risk factors for progression is the degree of proteinuria (see Chapter 76). Progression is uncommon if there is sustained proteinuria of less than 2 g/day. The risk increases in proportion to the severity of

Acute Kidney Injury in Nephrotic Syndrome
Prerenal failure due to volume depletion
Acute tubular necrosis due to volume depletion and/or sepsis
Intrarenal edema
Renal vein thrombosis
Transformation of underlying glomerular disease (e.g., crescentic nephritis superimposed on membranous nephropathy)
Adverse effects of drug therapy
Acute allergic interstitial nephritis secondary to various drugs, including diuretics
Hemodynamic response to nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs)

Figure 15.16 Acute Kidney Injury in nephrotic syndrome. Problems to consider in the evaluation of acute deterioration in renal function in nephrotic syndrome.

Figure 15.17 Proteinuria and prognosis in glomerular disease. The influence of heavy proteinuria on long-term renal function in 253 patients with primary glomerular disease at Manchester Royal Infirmary, United Kingdom. Heavy proteinuria at any time during long-term follow-up substantially worsens the prognosis even without frank nephrotic syndrome. (Courtesy Dr. C. D. Short.)

the proteinuria (Fig. 15.17), with marked risk of progression when protein excretion is more than 5 g/day. This may be because proteinuria identifies patients with severe glomerular injury, but there is also experimental and clinical evidence that proteinuria *per se* may be toxic, especially to the tubulointerstitium.¹⁶ In several experimental models, measures that reduce proteinuria, such as the use of ACE inhibitors, also prevent tubulointerstitial disease and progressive renal failure.

NEPHRITIC SYNDROME

In nephrotic syndrome, the glomerular injury is manifested primarily as an increase in permeability of the capillary wall to protein. By contrast, in the nephritic syndrome, there is evidence

Differentiation Between Nephrotic Syndrome and Nephritic Syndrome		
Typical Features	Nephrotic	Nephritic
Onset	Insidious	Abrupt
Edema	++++	++
Blood pressure	Normal	Raised
Jugular venous pressure	Normal/low	Raised
Proteinuria	++++	++
Hematuria	May/may not occur	+++
Red cell casts	Absent	Present
Serum albumin	Low	Normal/slightly reduced

Figure 15.18 Differentiation between nephrotic syndrome and nephritic syndrome.

of glomerular inflammation resulting in a reduction in GFR, non-nephrotic proteinuria, edema and hypertension (secondary to sodium retention), and hematuria with red cell casts.

The classic nephritic syndrome presentation is that seen with acute poststreptococcal GN in children. These children usually present with rapid onset of oliguria, weight gain, and generalized edema during a few days. The hematuria results in brown rather than red urine, and clots are not seen. The urine contains protein, red cells, and red cell casts. Because proteinuria is rarely in the nephrotic range, serum albumin concentration is usually normal. Circulating volume increases with hypertension, and pulmonary edema follows without evidence of primary cardiac disease.

The distinction between typical nephrotic syndrome and nephritic syndrome is usually straightforward on clinical and laboratory grounds (Fig. 15.18), and the use of these clinical descriptions is particularly helpful in the approach to patients with suspected GN at first presentation, helping to narrow the differential diagnosis. However, the classification systems are imperfect, and patients with certain glomerular disease patterns, for example, MPGN, may present with either a nephrotic or a nephritic picture.

Etiology

The primary glomerular diseases associated with the nephritic syndrome and the serologic tests helpful in diagnosis are shown in Figure 15.19. The classification is even more challenging than for nephrotic syndrome as some diseases are identified by histology (IgA nephropathy), others by serology and histology (ANCA-associated vasculitis and lupus nephritis), and others by etiology (postinfectious GN).

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive GN (RPGN) describes the clinical situation in which glomerular injury is so acute and severe that renal function deteriorates during days or weeks. The patient may present as a uremic emergency, with nephritic syndrome that is not self-limited but moves on rapidly to renal failure, or with rapidly deteriorating renal function when being investigated for

Common Glomerular Diseases Presenting as Nephritic Syndrome		
Disease	Associations	Serologic Tests Helpful in Diagnosis
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	ASO titer, streptozyme antibody
Other postinfectious disease		
Endocarditis	Cardiac murmur	Blood cultures, C3 ↓
Abscess	—	Blood cultures, C3, C4 normal or increased
Shunt	Treated hydrocephalus	Blood cultures, C3 ↓
IgA nephropathy	Upper respiratory or gastrointestinal infection	Serum IgA ↑
Systemic lupus	Other multisystem features of lupus	Antinuclear antibody, anti-double-stranded DNA antibody, C3 ↓, C4 ↓

Figure 15.19 Common glomerular diseases presenting as nephritic syndrome.

Common Glomerular Diseases Presenting as Rapidly Progressive Glomerulonephritis		
Disease	Associations	Serologic Tests Helpful in Diagnosis
Goodpasture's syndrome	Lung hemorrhage	Anti-glomerular basement membrane antibody (occasionally antineutrophil cytoplasmic antibodies [ANCA] present)
Vasculitis		
Wegener's granulomatosis	Upper and lower respiratory involvement	Cytoplasmic ANCA
Microscopic polyangiitis	Multisystem involvement	Perinuclear ANCA
Pauci-immune crescentic glomerulonephritis	Renal involvement only	Perinuclear ANCA
Immune complex disease		
Systemic lupus erythematosus	Other multisystem features of lupus	Antinuclear antibody, anti-double-stranded DNA antibody, C3 ↓, C4 ↓
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	ASO titer, streptozyme antibody, C3 ↓, C4 normal
IgA nephropathy/Henoch-Schönlein purpura	Characteristic rash ± abdominal pain in HSP	Serum IgA ↑ (30%), C3 and C4 normal
Endocarditis	Cardiac murmur; other systemic features of bacteremia	Blood cultures, ANCA (occasionally) C3 ↓, C4 normal

Figure 15.20 Common glomerular diseases presenting as rapidly progressive glomerulonephritis. Note the overlap between these diseases and those in Figure 15.19. A number of glomerular diseases may present with either nephritic syndrome or rapidly progressive glomerulonephritis.

extrarenal disease (many of the patterns of GN associated with RPGN occur as part of a systemic immune illness).

The histologic counterpart of RPGN is crescentic GN. The proliferative cellular response seen outside the glomerular tuft but within Bowman's space is known as a crescent because of its shape on histologic cross section (see Fig. 16.9). Typically, the glomerular tuft also shows segmental necrosis, or focal segmental necrotizing GN; this is particularly characteristic of the vasculitis syndromes.

The term RPGN is therefore often used to describe acute deterioration in renal function in association with a crescentic nephritis. Unfortunately, not all patients with a nephritic urine sediment and acute kidney injury (AKI) will fit this syndrome. For example, AKI may also occur in milder forms of glomerular disease if it is complicated by accelerated hypertension, renal vein thrombosis, or acute tubular necrosis. This emphasizes the need to obtain histologic confirmation of the clinical diagnosis.

Etiology

The primary glomerular diseases associated with RPGN and helpful serologic tests are shown in Figure 15.20. As with nephritic syndrome, different assessment methods are useful for different diseases causing RPGN.

PROGRESSIVE CHRONIC KIDNEY DISEASE

In most types of chronic GN, a proportion of patients (often between 25% and 50%) will have slowly progressive renal impairment. If no clinical event early in the course of the disease brings them to medical attention, patients may present late with established hypertension, proteinuria, and renal impairment. In very long standing GN, the kidneys shrink (but remain smooth and symmetric). Renal biopsy at this stage is more hazardous and less likely to provide diagnostic material. Light microscopy often shows nonspecific features of end-stage kidney disease, consisting of focal or global glomerulosclerosis and dense tubulointerstitial fibrosis, and it may not be possible to define with confidence that a glomerular disease was the initiating renal injury, let alone define the pattern further. Immunofluorescence may be more helpful; in particular, mesangial IgA may be present in adequate amounts to allow a diagnosis of IgA nephropathy to be made. However, when renal imaging shows small kidneys, only rarely will biopsy be appropriate. For this reason, chronic GN has often been a presumptive diagnosis in patients presenting late with shrunken kidneys, proteinuria, and renal impairment. This is imprecise and in the past has led to an overestimate of the frequency of GN as a cause of end-stage renal disease in registry data. GN should be diagnosed only if there is confirmatory histologic evidence.

TREATMENT OF GLOMERULAR DISEASE

General Principles

Before any therapeutic decisions, it should always be ascertained that glomerular disease is primary and that no specific therapy is available. For example, treatment of an underlying infection or tumor may result in remission of GN. In the remaining cases, both general supportive treatment¹⁷ (see Chapter 77) and disease-specific therapy should be considered. Supportive treatment includes measures to treat blood pressure, reduce proteinuria, control edema, and address other metabolic consequences of nephrotic syndrome. If successful, these relatively nontoxic therapies can prevent the need for immunosuppressive drugs, which have multiple potential side effects. Supportive therapy is usually not necessary in corticosteroid-sensitive MCD with rapid remission or in patients with IgA nephropathy, Alport's syndrome, or thin basement membrane nephropathy as long as they exhibit neither proteinuria nor hypertension.

Hypertension

Hypertension is very common in GN; it is virtually universal as chronic GN progresses toward end-stage renal disease and is the key modifiable factor in preserving renal function (see also Chapter 77). Sodium and water overload is an important part of the pathogenetic process, and high-dose diuretics with moderate dietary sodium restriction are usually an essential part of the treatment. As in other chronic renal diseases, the aim of blood pressure control is not only to protect against the cardiovascular risks of hypertension but also to delay progression of the renal disease. The ideal target blood pressure is not finally established, but in the Modification of Diet in Renal Disease (MDRD) study, patients with proteinuria (>1 g/day) had a better outcome if their blood pressure was reduced to 125/75 mm Hg rather than to the previous standard of 140/90 mm Hg.^{18,19} There are strong theoretical and experimental reasons for ACE inhibitors and ARBs to be first-choice therapy, and this is now well documented in clinical studies.²⁰⁻²² Nondihydropyridine calcium channel blockers may also have a beneficial effect on proteinuria as well as on blood pressure. As in primary hypertension, lifestyle modification (salt restriction, weight normalization, regular exercise, and smoking cessation) should be an integral part of the therapy. If target blood pressure cannot be achieved with these measures, antihypertensive therapy should be stepped up according to current guidelines (see Chapter 35).

Treatment of Proteinuria

Besides hypertension, proteinuria represents the second key modifiable factor to preserve GFR (see also Chapter 77). Most studies suggest that the progressive loss of renal function observed in many glomerular diseases can largely be prevented if proteinuria can be reduced to levels below 0.5 g/day. This may be because many of the measures to reduce protein excretion, such as the use of ACE inhibitors or ARBs, also reduce glomerular hypertension, which contributes to progressive renal failure. However, there is also increasing evidence that proteinuria or factors present in proteinuric urine *per se* may be toxic to the tubulointerstitium.¹⁶ Finally, in nephrotic patients, a reduction of proteinuria to a non-nephrotic range can induce serum proteins to rise, with alleviation of many of the metabolic complications of nephrotic syndrome.

Most of the agents used to reduce urinary protein excretion do so hemodynamically, either by blocking efferent arteriolar constriction (ACE inhibitors or ARBs) or by reducing preglomerular pressure (most other classes of antihypertensives). Some of the agents, such as ACE inhibitors and ARBs, may also have direct effects on reducing the increased glomerular capillary wall permeability. A consequence of this type of therapy is a reduction in GFR; however, in general, the decrease in GFR is of a lower magnitude than the decrease in protein excretion. The antiproteinuric agents of choice are ACE inhibitors and ARBs, which reduce proteinuria by an average of 40% to 50%, particularly if the patient is on dietary salt restriction. There is little clinical evidence to suggest that ACE inhibitors differ from ARBs in this respect. The combination of the two may result in additive antiproteinuric activity but increases the risk of AKI.²³ In addition, whereas other classes of antihypertensive agents will reduce proteinuria coincident with a decrease in systemic blood pressure (particularly the nondihydropyridine calcium channel blockers such as diltiazem), both ACE inhibitors and ARBs usually reduce proteinuria independent of blood pressure. If doses are increased slowly to minimize symptomatic hypotension, treatment with ACE inhibitors and ARBs is usually possible in the normotensive proteinuric patient. Increasing the dose of ACE inhibitors or ARBs may further reduce proteinuria without lowering blood pressure, which may indicate the inefficacy of other antihypertensive drugs in blocking the stimulated intrarenal renin-angiotensin system. Common side effects include hyperkalemia in patients with advanced renal failure, which may necessitate a loop diuretic but rarely should lead to cessation of ACE inhibitors and ARBs, and cough in the case of ACE inhibitors, in which case ARBs should be used instead. Because ACE inhibitors and ARBs lower GFR (see previous discussion), a 10% to 30% increase in serum creatinine concentration may be observed. Unless serum creatinine concentration continues to increase, this moderate increase reflects the therapeutic effect of these medications and should not prompt their withdrawal.

NSAIDs lessen proteinuria by reducing intrarenal prostaglandin production and dipyridamole through adenosine-mediated afferent arteriolar vasoconstriction. Given the safety of the therapies discussed previously, as well as the risk with NSAIDs of profound decreases in GFR, salt retention, and diuretic resistance, they are rarely used.

A low-protein diet will lessen proteinuria but must be advised with great care because of the risk of malnutrition. Adequate compensation must be made for urine protein losses,²⁴ and the patient must be carefully monitored for evidence of malnutrition (see Chapter 83). Whether a low-protein diet is still antiproteinuric in patients treated with a full-dose ACE inhibitor or ARB is not established.

Treatment of Hyperlipidemia

Treatment of hyperlipidemia in patients with glomerular disease should usually follow the guidelines that apply to the general population to prevent cardiovascular disease. It may also be that statin therapy protects from a decrease in GFR, although this is not firmly established. Dietary restriction alone has only modest effects on hyperlipidemia in glomerular disease, in particular in nephrotic syndrome. Side effects of some medications, for example, rhabdomyolysis provoked by fibrates, occur more frequently in patients with renal failure. The addition of bile acid sequestrants, such as cholestyramine, may lower LDL further

and increase HDL but is usually not tolerated because of gastrointestinal effects.

Avoidance of Nephrotoxic Substances

Apart from NSAIDs, which may induce AKI, particularly in patients with preexisting renal impairment and dehydration, other nephrotoxic substances, such as radiocontrast agents, some cytotoxic drugs, and antibiotics (e.g., aminoglycoside antibiotics), should also be used with caution in patients with glomerular disease and renal impairment or nephrotic syndrome.

Special Therapeutic Issues in Patients with Nephrotic Syndrome

Treatment of Nephrotic Edema

In contrast to the lack of therapies in the past (Fig. 15.21), the mainstays of treatment nowadays are diuretics accompanied by moderate dietary sodium restriction (60 to 80 mmol/24 h). Nephrotic patients are diuretic resistant even if GFR is normal. Loop diuretics must reach the renal tubule to be effective, and transport from the peritubular capillary requires protein binding, which is reduced in hypoalbuminemia; once the drug reaches the renal tubule, it will become 70% bound to protein present in the urine and therefore be less effective. Oral diuretics with twice-daily administration are usually preferred, given the longer therapeutic effect compared with intravenous diuretics. However, in severe nephrosis, gastrointestinal absorption of the diuretic may be uncertain because of intestinal wall edema, and intravenous diuretic, by bolus injection or infusion, may be necessary to provoke an effective diuresis. Alternatively, combining a loop diuretic with a thiazide diuretic or with metolazone may overcome diuretic resistance. The characteristics of different diuretics are discussed in Chapter 7. Significant hypovolemia is not often a clinical problem, provided fluid removal is controlled and gradual. Daily weight is the best measurement of progress. Nephrotic children are much more prone to hypovolemic shock than adults are. A stepwise approach to diuretic use is required, aiming at fluid removal in adults of no more than 2 kg daily, moving on to the next drug level if this is not achieved (Fig. 15.22).

Correction of Hypoproteinemia

In view of the problems associated with either increased protein administration or dietary protein restriction in nephrotic patients (see previous discussion), adequate dietary protein should be ensured (0.8 to 1 mg/kg per day) with a high carbohydrate intake to maximize use of that protein. When there is very heavy proteinuria, the amount of urinary protein loss should be added to dietary protein intake.

In the rare setting in which proteinuria is so severe that the patient is dying of the complications of nephrotic syndrome, one may have to resort to nephrectomy to prevent continued protein losses. This may be done as a medical nephrectomy: the deliberate use of NSAIDs combined with ACE inhibitors and diuretic to lessen proteinuria by provoking AKI. If medical nephrectomy alone does not adequately reduce proteinuria, bilateral renal artery embolization can be considered. It may be a painful procedure and is not always as successful as might be expected (perhaps because of collateral arterial supply to the kidneys, which is not blocked by the embolization). A final alternative is bilateral nephrectomy, which carries significant mortality in these severely ill hypoproteinemic patients and is rarely used

Figure 15.21 Treatment of nephrotic edema before the availability of diuretics. Edema in nephrotic syndrome was very difficult to treat. This child with anasarca, pictured in 1953, stands in a bowl while edema fluid drips out through small tubes placed through needles in the skin of the feet. This was nevertheless effective treatment. The two pictures of the same child were taken 4 days apart, during which time the child lost 4.5 kg (10 lb), or 18% of body weight. (Courtesy Dr. Robert Vernier.)

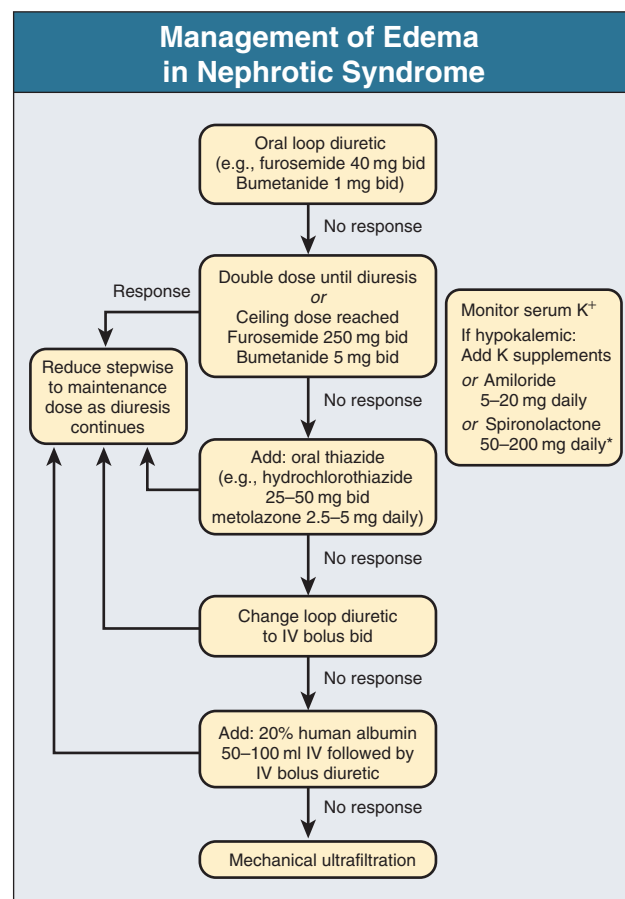

Figure 15.22 Management of edema in nephrotic syndrome. Edema is often diuretic resistant, but the response is not predictable. Therefore, stepwise escalation of therapy is appropriate until diuresis occurs. Even when there is anasarca, diuresis should not proceed faster than 2 kg/day in adults to minimize the risk of clinically significant hypovolemia. Mechanical ultrafiltration is rarely required for nephrotic edema unless there is associated renal insufficiency. *Spironolactone is less effective in nephrotic syndrome than in cirrhosis and is often poorly tolerated because of gastrointestinal side effects. Spironolactone should be used with great caution if the GFR is very low.

in adults, although it is a conventional part of management of infants with congenital nephrotic syndrome.

Treatment of Hypercoagulability

The risk of thrombotic events becomes progressively more important as serum albumin values decrease to less than 2.5 g/dl. Immobility as a consequence of edema or intercurrent illness further aggravates the risk. Prophylactic low-dose anticoagulation (e.g., heparin 5000 units subcutaneously twice daily) is indicated at times of high risk, such as relative immobilization in the hospital and albumin levels between 2 and 2.5 g/dl. Full-dose anticoagulation with low-molecular-weight heparin or warfarin should be considered if serum albumin decreases to less than 2 g/dl^{11,25} and is mandatory if a thrombosis or pulmonary embolism is documented. Heparin is used for initial anticoagulation, but an increased dose may be needed because part of the action of heparin depends on antithrombin III, which is often reduced in the plasma in nephrotic patients. Warfarin (target international normalized ratio 2 to 3) is the long-term treatment of choice but should be manipulated with special care because of altered protein binding, which may require dose reductions.

Management of Infection

A high order of clinical suspicion for infection is vital in nephrotic patients. Especially in nephrotic children, ascitic fluid should be examined microscopically and cultured if there is any suspicion of systemic infection. Bacteremia is common even if clinical signs are localized. ESR is unhelpful, but an elevated C-reactive protein level may be more informative. Parenteral antibiotics should be started once culture specimens are taken, and the regimen should include benzylpenicillin (to cover pneumococci). If repeated infections occur, serum immunoglobulins should be measured. If serum IgG is less than 600 mg/dl, there is evidence in an uncontrolled study that infection risk is reduced by monthly administration of intravenous immune globulin (10 to 15 g) to keep the IgG levels above 600 mg/dl.²⁶

Disease-Specific Therapies

Specific treatments for glomerular diseases are discussed in the subsequent chapters; the general principles are discussed here. As most glomerular disease is thought to have an immune pathogenesis, treatment has generally consisted of immunosuppressive therapy aimed at blocking of both the systemic and local effects. In the setting in which glomerular disease results from an ineffectual elimination of a foreign antigen, treatment involves measures to eliminate this antigen whenever possible (such as antibiotics in endocarditis-associated GN or interferon alfa for cryoglobulinemia associated with hepatitis C infection).

In general, the more severe and acute the presentation of GN, the more successful is immune treatment; there has been little success for immunosuppression in chronic GN. When renal function is declining rapidly, there is little to lose and the toxicity of intensive regimens becomes acceptable for a short period but would be unacceptable if prolonged. Furthermore, the nonspecific nature of most immune treatments results in widespread interruption of immune and inflammatory events at multiple levels. In the acute situation, this broad-based attack is a virtue; in more indolent disease, more specific treatment is needed but is unavailable. Despite great increases in the understanding of immune mechanisms in glomerular disease since the 1970s, immune therapies are not yet much more specific and precise. The mainstays of treatment remain agents that were available in

the 1960s: corticosteroids, azathioprine, and cyclophosphamide. Other newer immunosuppressive agents developed for use in transplantation, including cyclosporine, tacrolimus, mycophenolate mofetil, and rapamycin, or those developed in oncology, including rituximab, have emerging indications in glomerular disease.

The use of immunosuppressive therapies to treat GN has certain drawbacks. In many diseases, treatment is based on small series, and good prospective controlled trials are lacking. Because of both the rarity and the variable natural history of GN, proof of efficacy for a particular therapy often requires a multicenter approach with prolonged follow-up, which is logistically difficult. If sufficient glomerular damage is present, proteinuria and progressive deterioration of renal function may occur by nonimmune pathways that may not be responsive to immunosuppressive therapies. Unfortunately, good noninvasive markers to assess disease activity are missing in most clinical circumstances. Given the frequent uncertainty of the response to immunosuppressive therapy, it becomes mandatory to weigh the potential benefits against the risks of therapy.

Immunosuppression may be associated with reactivation of tuberculosis and hepatitis B infection and can also lead to a hyperinfection syndrome in patients with *Strongyloides* species infection. Therefore, high-risk patients should be screened for these diseases before embarking on therapy.

Alkylating agents, such as cyclophosphamide and chlorambucil, have considerable toxicity. In the short term, leukopenia is common, as is alopecia, although hair will regrow within a few months of discontinuation of therapy. These agents can cause infertility (observed in adults with cumulative doses of cyclophosphamide >200 mg/kg and chlorambucil 10 mg/kg). There is also an increased incidence of leukemias (observed with total doses of cyclophosphamide >80 g and chlorambucil 7 g). Cyclophosphamide is also a bladder irritant, and treatment can result in hemorrhagic cystitis and bladder carcinoma, particularly after therapy lasting more than 6 months.²⁷ Irritation of the bladder is caused by a metabolite, acrolein. The effect can be minimized in patients receiving intravenous cyclophosphamide by enforcing a good diuresis and administering mesna. The dose of mesna (mg) should equal the dose of cyclophosphamide (mg); 20% is given intravenously with the intravenous cyclophosphamide, and the remaining 80% should be given in two equal oral doses at 2 and 6 hours by intravenous infusion at the same dose as the cyclophosphamide. Chlorambucil and cyclophosphamide also require dose reduction in the setting of renal insufficiency. Given all these concerns, oral treatment with these agents should ideally be limited to 12 weeks.

The modes of action and potential adverse effects of corticosteroids, azathioprine, and other immunosuppressives occasionally used in glomerular disease are discussed further in Chapter 97.

Introduction to Glomerular Disease: Histologic Classification and Pathogenesis

Richard J. Johnson, Jürgen Floege, John Feehally

HISTOLOGIC CLASSIFICATION

Glomerular disease may have a wide variety of causes and clinical presentations (see Chapter 15). Some glomerular diseases are given the generic title of glomerulonephritis (GN), which implies an immune or inflammatory pathogenesis. Although there are some situations in which specific diagnosis can be made on the basis of clinical presentation and laboratory tests, a renal biopsy is useful for both classification and prognosis in most cases. Ideally, the renal biopsy specimen should be examined by light microscopy, immunofluorescence, and electron microscopy. By use of this approach, a histologic pattern can be diagnosed. Some histologic patterns can be coupled with other laboratory test results to identify a specific etiology, but the condition is idiopathic in many cases. However, because treatments are often developed for specific histologic patterns, this approach is currently favored in the management of these disorders.

HISTOPATHOLOGY

The full assessment of a renal biopsy specimen requires light microscopy, electron microscopy, and examination for deposits of complement and immunoglobulin by immunofluorescence or immunoperoxidase techniques.

Light Microscopy

In GN, the dominant but not the only histologic lesions are in glomeruli (Fig. 16.1). GN is described as focal (only some glomeruli are involved) or diffuse. In any individual glomerulus, injury may be segmental (affecting only part of any glomerulus) or global. There is a potential for sampling error in a renal biopsy: the extent of a focal lesion may be misjudged in a small biopsy specimen, and sections through glomeruli may miss segmental lesions. Lesions may also be hypercellular due to either an increase in endogenous endothelial or mesangial cells (termed proliferative) or an infiltration of inflammatory leukocytes (termed exudative). Severe acute inflammation may produce glomerular necrosis, which is often segmental. The walls of the glomerular capillaries can also be thickened by a number of processes, which include an increase in glomerular basement membrane (GBM) material and immune deposits. Segmental sclerosis and scarring may also occur and are characterized by segmental capillary collapse with the accumulation of hyaline material and mesangial matrix and often with attachment of the

capillary wall with Bowman's capsule (synechiae or adhesion formation).

The classic stains used in light microscopy include hematoxylin and eosin and the periodic acid–Schiff (PAS) reaction, which is particularly good for evaluating cellularity and matrix expansion. More specific stains include methenamine silver, which stains GBM and other matrix black. It may, for example, reveal a double contour to the GBM because of the interposition of cellular material, or it may show increased mesangial matrix not easily seen with other techniques. Trichrome staining is also useful to show areas of scarring (stains blue), whereas immune deposits stain red.

Crescents are inflammatory collections of cells in Bowman's space. Crescents develop when severe glomerular injury results in local rupture of the capillary wall or Bowman's capsule, allowing plasma proteins and inflammatory material to enter into Bowman's space. Crescents consist of proliferating parietal and visceral epithelial cells, infiltrating fibroblasts, and lymphocytes and monocytes-macrophages, often with local fibrin deposition. They are called crescents because of their appearance when the glomerulus is cut in one plane for histology. They are destructive and rapidly increasing in size and may lead to glomerular tuft occlusion (see Fig. 16.1). If the acute injury is stopped, the crescents may either resolve with restitution of normal morphology or heal by fibrosis, causing irreversible loss of renal function. Crescents are most commonly observed with vasculitis, in Goodpasture's disease, and in severe acute GN of any etiology.

Tubulointerstitial injury and fibrosis can also accompany GN and may play an important role in the prognosis (see Chapter 76).

Immunofluorescence and Immunoperoxidase Microscopy

Indirect immunofluorescence and immunoperoxidase staining are both used to identify immune reactants (Fig. 16.2). Examination consists of staining for immunoglobulins IgG, IgA, and IgM; for components of the complement system (usually C3, C4, and C1q); and for fibrin, which is commonly observed in crescents and in capillaries in thrombotic disorders (such as hemolytic-uremic syndrome and the antiphospholipid syndrome). Immune deposits may occur along the capillary loops or in the mesangium. They may be continuous (linear) or discontinuous (granular) along the capillary wall or in the mesangium.

Characteristic patterns of glomerular disease illustrating the range of histologic appearances and the descriptive terms used. **A**, Normal glomerulus: minimal change disease. **B**, Segmental sclerosis: focal segmental glomerulosclerosis. **C**, Diffuse mesangial hypercellularity: IgA nephropathy. **D**, Diffuse endocapillary hypercellularity: poststreptococcal glomerulonephritis. **E**, Segmental necrosis: renal vasculitis. **F**, Crescent formation: anti-glomerular basement membrane disease. (**A** and **B**, Hematoxylin-eosin; **C**, **D**, and **F**, periodic acid-Schiff; **E**, trichrome.)

Electron Microscopy

Electron microscopy (EM) is valuable for defining the morphology of the basement membranes (abnormal in some forms of hereditary nephropathy, e.g., Alport's syndrome and thin basement membrane nephropathy [see Chapter 46]) and also for identifying fibrils (e.g., in amyloidosis) or tubuloreticular intracellular structures (e.g., in lupus nephritis). EM is also useful for localizing the site of immune deposits (which are usually homogeneous and electron dense; Fig. 16.3). Electron-dense deposits are seen in the mesangium or along the capillary wall on the subepithelial or subendothelial side of the GBM. Uncommonly, the electron-dense material lies linearly within the GBM. The

sites of immune deposits are helpful in the classification of the types of GN.

GENERAL MECHANISMS OF GLOMERULAR INJURY

Proteinuria

Proteinuria is the hallmark of glomerular disease. Although there is some evidence that the endothelial glycocalyx, the GBM, and the podocytes may repel proteins in part through their highly negative charge (proteins are mostly negatively charged as well) from entering Bowman's space, a major barrier for protein is in

Figure 16.2 Pathology of glomerular disease: immunofluorescence microscopy. Common patterns of glomerular staining found by immunofluorescence. **A**, Linear capillary wall IgG: anti-glomerular basement membrane disease. **B**, Fine granular capillary wall IgG: membranous nephropathy. **C**, Coarse granular capillary wall IgG: membranoproliferative glomerulonephritis type I. **D**, Granular mesangial IgA: IgA nephropathy.

the slit diaphragm between the podocyte foot processes (Fig. 16.4).¹ The slit diaphragm consists of several transmembrane proteins that extend from adjacent interdigitating foot processes to form a zipper-like scaffold on the outer side of the GBM (Fig. 16.5).¹

The importance of the slit diaphragm in proteinuric states has been documented in numerous hereditary types of nephrotic syndrome in which the mutations involve various slit diaphragm proteins (see Chapter 19).² These diseases usually present in childhood as a type of corticosteroid-resistant minimal change disease (MCD) or focal segmental glomerulosclerosis (FSGS). However, an exception is autosomal recessive corticosteroid-resistant nephrotic syndrome, in which the homozygous mutation in podocin (*NPHS2*) presents in childhood but the heterozygous mutation, when it coexists with the p.R229Q variant polymorphism, may be due to a mutation that under certain circumstances may not clinically manifest until young adulthood (20 to 40 years old).³

Whereas proteinuria may be the consequence of direct injury to the slit diaphragm, in most cases proteinuria may be due to injury to the podocyte. When the podocyte is injured, it will undergo shape change with swelling and loss or fusion of the foot processes. Filtration is actually reduced at sites where the foot processes fuse (which may account for the reduction of the filtration coefficient K_f seen in nephrotic syndrome), but there are gaps where the podocytes are detached from the GBM. It is at these sites that massive protein filtration occurs; structurally, the capillary wall defects are likely to correspond to the large pores noted in functional studies (Fig. 16.6).⁴

Podocyte immaturity can also result in nephrotic syndrome. Congenital nephrotic syndrome with mesangial sclerosis has recently been linked with mutations in phospholipase C epsilon gene (*PLCE1*), which is important in podocyte development.⁵

Antibody and Antigen

Many glomerular diseases are associated with positive staining for immunoglobulins, often with components of the complement system, and with the presence of electron-dense deposits by EM. These findings are thought to represent immune complexes. Experimentally, immune complexes can localize in glomeruli by two major mechanisms. In some conditions, such as mesangial proliferative GN, membranoproliferative GN (MPGN), and lupus nephritis, the immune complexes are thought to originate in the circulation and to be passively trapped in the mesangium or subendothelial areas. In contrast, circulating immune complexes cannot readily pass across the GBM, and the presence of IgG in membranous nephropathy is thought to be due to direct binding of antibody to antigens constitutively expressed on the podocyte or to an antigen that may first be “trapped” or bound at this site (*in situ* formation).⁶ Complement activation can also occur in the absence of antigen (resulting in the ribbon deposits noted in patients with dense deposit disease (DDD, previously known as type II MPGN). Under some circumstances, antigens may also deposit that directly activate the alternative pathway of complement in the absence of IgG; this may occur in some forms of poststreptococcal GN (PSGN). Antibody with aberrant characteristics may also aggregate and activate complement in the

Some characteristic patterns of electron-dense deposits and GBM abnormalities seen in glomerular disease. **A**, Normal. **B**, Foot process effacement: minimal change disease (*arrows*). **C**, GBM thickening and splitting: Alport's syndrome. CL, capillary lumen; BS, Bowman's space. **D**, Subendothelial electron-dense deposits (*arrows*): membranoproliferative glomerulonephritis type I. **E**, Subepithelial electron-dense deposits (*arrows*): membranous nephropathy. **F**, Mesangial electron-dense deposits (*arrows*): IgA nephropathy.

Figure 16.4 Mechanisms of proteinuria. Normally negatively charged proteins, such as albumin, are retarded by the negatively charged proteins in the endothelium (sialoglycoproteins) and basement membrane (heparan sulfate proteoglycans) as well as by a size barrier in the GBM and at the slit diaphragm. In most proteinuric states, the podocytes are injured, leading to foot process swelling and injury to the slit diaphragm; in these situations, protein (albumin) can pass through the GBM and the gaps between the fused foot processes.

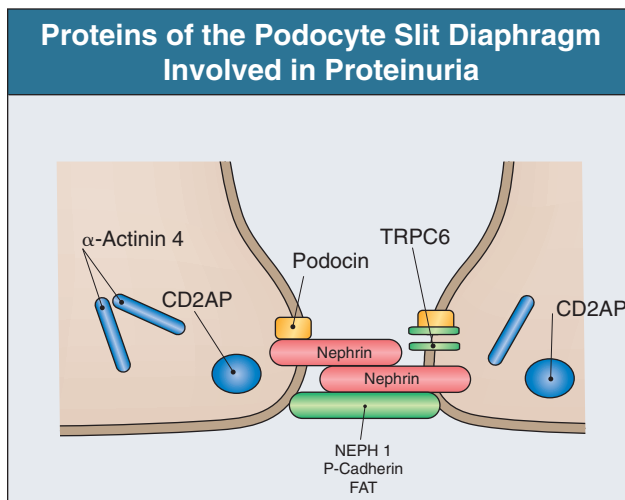

Figure 16.5 Proteins of the podocyte slit diaphragm involved in proteinuria. Several inherited glomerular diseases involve mutations of antigens associated with the slit diaphragm. These include nephrin (congenital nephrotic syndrome of the Finnish type), podocin (autosomal recessive FSGS), and α -actinin and TRPC6 (both associated with autosomal dominant FSGS). In addition, mutation of CD2-associated protein results in nephrotic syndrome in mice. (Modified from reference 1.)

absence of antigen (such as may occur in some cases of IgA nephropathy in which aberrantly glycosylated IgA may occur).⁷

Immune complexes are normally removed from the circulation by binding of the complex to the C3b receptors on erythrocytes; the immune complexes are then removed and degraded during transit of the erythrocytes in the liver and spleen. If antigenemia persists or clearance of complexes is impaired (such as in chronic liver disease), immune complexes may deposit in the glomerulus by binding to Fc receptors on mesangial cells or by passive deposition in the mesangium or subendothelial space. Physical characteristics of the complexes may also favor

Figure 16.6 Glomerular permeability in nephrotic syndrome. A dextran sieving curve showing the relative glomerular permeability of different-sized dextrans in normal subjects and nephrotic patients with membranous nephropathy and minimal change disease. Nephrotic subjects actually have a lower fractional dextran clearance for small dextrans (26 to 48 Å [2.6 to 4.8 nm]) but have an increased clearance for dextrans of larger molecular weight (52 to 60 Å [5.2 to 6.0 nm]). This is consistent with large pores appearing in the GBM. (Modified from reference 4.)

deposition, including avidity, charge, and size. Measurement of circulating immune complexes in patients with GN has not, however, shown close correlation with glomerular events and hence is not typically performed.

In some glomerular diseases, the target antigen has been identified (Fig. 16.7). Whereas the immune deposits may be associated with a specific antigen, glomerular diseases can also develop as a consequence of infection with organisms releasing superantigens that cause a polyclonal activation of B cells. The classic organism responsible for superantigen-associated GN is *Staphylococcus aureus*, and the pattern of immune deposits often includes the presence of both IgG and IgA. In other situations, infections may initiate an immune response that then results in cross-reaction with endogenous antigens. Studies suggest that this type of molecular mimicry may be responsible for both Goodpasture's syndrome and certain types of vasculitis (see Fig. 16.7).^{8,9} Once an immune response is initiated, the local injury may lead to the release of additional antigens that may initiate an immune response (epitope spreading). In anti-GBM disease, in which the antigen is the $\alpha 3$ chain of type IV collagen, the antigen is present in the lung alveolar basement membrane but is normally sequestered. However, in tobacco smokers, the inhalation results in oxidative injury with exposure of the $\alpha 3$ chain, allowing the binding of antibody.¹⁰ This may explain why lung involvement is almost exclusively observed in smokers in this disease.

Complement

The complement system is also often activated in glomerular disease (Fig. 16.8). Complement can be activated through three pathways. Classical activation involves the binding of C1q to the Fc region of antibody in IgG- and IgM-containing immune

Antigens Identified in Glomerulonephritis	
Poststreptococcal GN	Streptococcal pyrogenic exotoxin B (SPEB), plasmin receptor
Anti-GBM disease	α 3 type IV collagen (likely induced by molecular mimicry)
IgA nephropathy	Possibly no antigen but rather polymerized polyclonal IgA (?superantigen driven)
Membranous nephropathy	Phospholipase A ₂ receptor (idiopathic), neutral endopeptidase (NEP) in podocyte (congenital), HBeAg (hepatitis associated)
<i>Staphylococcus aureus</i> –associated GN	Staphylococcus superantigens induce polyclonal response; not necessarily antigen in glomeruli
Membranoproliferative GN	HCV and HBsAg in hepatitis-associated MPGN
ANCA-associated vasculitis	Proteinase 3 (c-ANCA) and myeloperoxidase (p-ANCA) in neutrophils; antibodies to lysosome-associated membrane protein 2 (LAMP-2) on endothelial cells (likely induced by molecular mimicry to fimbriated bacterial antigens)

Figure 16.7 Antigens identified in glomerulonephritis.

complexes and can result in reduced serum C4 and C3. This is common in lupus nephritis, type I MPGN, and cryoglobulinemic MPGN. Complement may also be activated by the alternative pathway, which is independent of immune complexes but triggered by polysaccharide antigens, polymeric IgA, injured cells, or endotoxins. This pathway appears to be activated in IgA nephropathy, DDD, and some cases of PSGN and membranous nephropathy. Serum complement levels are generally normal in both IgA nephropathy and membranous nephropathy; but in DDD and PSGN, the C3 is typically low, but C4 is normal. In DDD, the activation of the alternative pathway may not involve an antigen *per se* but rather may be due to an IgG auto-antibody (“nephritic factor”) that stabilizes the C3 convertase, resulting in its activation (see Chapter 21). Complement can also be activated through the mannose-binding pathway initiated by mannose-binding lectin, which has a similar structure to C1q. The role of the mannose-binding pathway in GN is emerging; it may be involved in some cases of IgA nephropathy.

Activation of the complement pathway has several consequences. Leukocyte recruitment is facilitated by the chemotactic factor C5a, and C3b binding is important in the binding and opsonization of the immune complexes by the infiltrating leukocytes. The terminal membrane attack complex of the cascade, C5b-9, inserts into cell membranes, where it can kill cells or activate them to secrete cytokines, oxidants, and extracellular matrix. C5b-9 is thought to be particularly important in mediating injury to the glomerular epithelial cell in membranous nephropathy, a disease in which immune deposits and complement activation occur in the subepithelial space. Complement

can also be activated in proteinuric urine as a consequence of amidation of C3 by ammonia, and this may have a role in mediating tubulointerstitial injury even in conditions not associated with immune complex formation. Studies have emphasized the importance of local synthesis of complement components by the tubular cells as a mechanism that may augment this process.¹¹

Activation of complement can occur easily, but it is usually tightly regulated by several complement regulatory proteins (see Fig. 16.8). It has recently been recognized that genetic absence or malfunction of factor H or other regulatory proteins can be associated with a hereditary form of MPGN or hemolytic-uremic syndrome.

Mechanisms of Immune Glomerular Injury

Two major mechanisms account for the presence of immune complexes in glomerular diseases. There may be ineffectual clearance of an antigen due to an impaired immune response, for example, in chronic viral infections such as hepatitis B and hepatitis C. Despite a strong humoral response, viral infection persists because the cell-mediated response required for elimination of these viruses from the liver is impaired. The consequence is a state of persistent antigenemia with circulating antigen-antibody complexes, which predisposes to glomerular injury. Eradication of the virus, for example, with interferon alfa therapy, can be associated with remission of the glomerular disease.

More commonly, glomerular disease may be due to autoimmunity. In health, a tension exists between the normal immune response to foreign antigen and tolerance, which is the cellular process that prevents an immune response to self antigen. Tolerance develops because self-reactive T and B cells are clonally deleted during fetal and neonatal life, although small numbers survive outside the thymus. Under certain conditions, these peripheral self-reactive T and B cells can be stimulated to generate a cellular and humoral response to a self antigen. Infection or toxins may play a role in initiating the response by releasing antigens from sequestered sites so they have access to T cells, by altering host proteins to make them more immunogenic, or by molecular mimicry, in which antibodies to an exogenous antigen (such as those present in an infecting organism) cross-react with a native protein. Activation of T cells may be further enhanced by the release of cytokines and lymphokines and the conversion of normally innocuous endogenous renal cells into antigen-presenting cells through the upregulated or *de novo* expression of HLA class II molecules.

A population of regulatory T cells (CD4⁺CD25⁺) has recently been shown to have a key role in controlling T cell responses and preventing the development of autoimmunity. These cells appear to be decreased in patients with anti-GBM disease at the time of presentation, which may play a role in the loss of tolerance. Indeed, in experimental anti-GBM nephritis, the administration of these cells can reduce glomerular damage by blocking T cell–dependent renal injury.¹²

Variations in HLA molecules and the T-cell receptor are under strong genetic influence. For that reason, immunogenetic associations, particularly between HLA expression and various patterns of GN, have been studied in great detail, but none of the reported associations is absolutely specific. For example, whereas HLA-DR2 identifies a powerful relative risk for the development of Goodpasture’s disease, it is still possible for the disease to develop without HLA-DR2, and most individuals with HLA-DR2 never develop this rare disease. Furthermore, HLA associations often differ among racial groups that have different

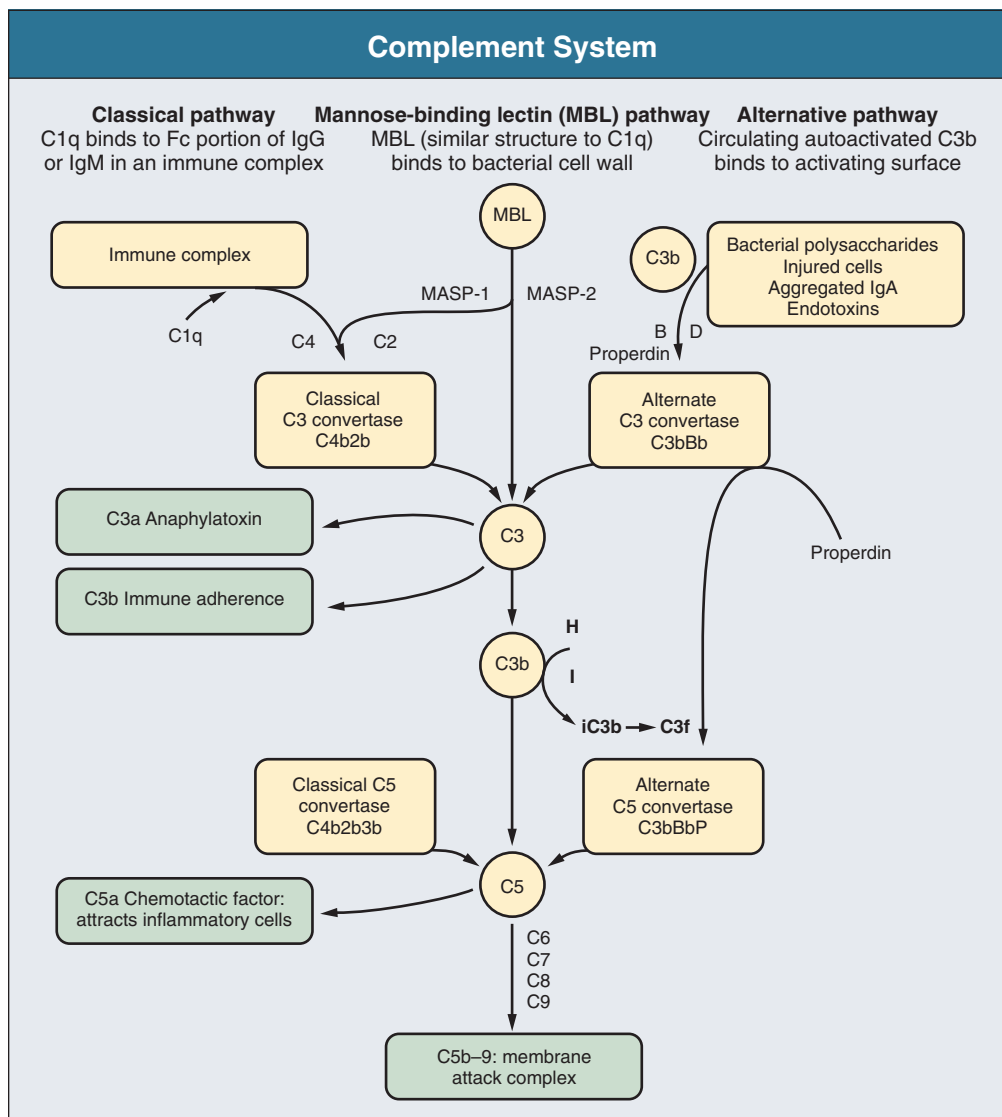

Figure 16.8 Complement system. The complement system is a self-amplifying cascade of proteins that generates a membrane attack complex, which is cytolytic; the cascade promotes inflammation by the activity of the fragments it produces. The amplifying cascades occur because activated fragments of the components combine to make convertase enzymes that degrade C3 and C5. The complement cascade is controlled in part by the very short active life of many of its components. There are also inhibitory regulatory proteins, most notably factors H and I inhibiting C3b. Activated fragments of any component are designated b (e.g., C3b); anaphylatoxic fragments are designated a (e.g., C5a). Inflammatory functions of complement components are shown in *green*. MASP, MBL-associated serine protease.

distributions of HLA. As yet, HLA associations have no practical diagnostic or therapeutic implications, and HLA typing is not needed in the clinical management of GN.

Inflammation

Infiltration by inflammatory cells is largely determined by the site of immune deposits. Immune deposits with direct access to the circulation (in particular those in subendothelial and basement membrane locations) are usually associated with a pronounced leukocyte accumulation. Mesangial deposits elicit an intermediate response, whereas immune deposits in the subepithelial space (such as in membranous nephropathy) generally are not associated with inflammatory cells.

In GN associated with subendothelial deposits, such as class IV lupus nephritis or MPGN, leukocyte infiltration is common. With acute injury, the predominant infiltrating cells are neutro-

phils, platelets, and monocytes; in chronic injury, the predominant cells are monocytes-macrophages and T cells. The primary mechanism for attracting these cells is the secretion of chemokines and the expression of leukocyte adhesion molecules by local endothelial and resident cells; local release of complement activation fragments (C5a) is also important.

In contrast to the immune complex mechanisms discussed previously, certain glomerular diseases develop primarily through cell-mediated immunity. For example, a direct role for T cells in mediating proteinuria and crescent formation has been shown in experimental crescentic nephritis.¹³ It is thought that T cells in the glomeruli, sensitized to endogenous or exogenous antigen, recruit macrophages, resulting in a local delayed-type hypersensitivity reaction. In certain animal models, CD8⁺ T cells have also been shown to mediate crescent formation, for example, through perforins (enzymes that act similarly to the complement membrane attack complex).

Proliferation, Apoptosis, and Fibrosis

Intrinsic glomerular cells (epithelial, mesangial, and endothelial) are also activated in various glomerular diseases. Mesangial cells, when activated, can become myofibroblast-like cells that proliferate and produce excessive extracellular matrix. Endothelial cells are a rich source of nitric oxide and other anti-inflammatory proteins, and injury to this cell population can result in the expression of leukocyte adhesion molecules and activation of the coagulation system. Podocytes are terminally differentiated cells; injury may result not only in proteinuria (see earlier discussion) but, when it is associated with apoptosis, also in glomerulosclerosis. Several key factors have been associated with glomerular injury, of which the most important appear to be transforming growth factor β that mediates matrix deposition, platelet-derived growth factor that mediates mesangial cell proliferation, and vascular endothelial growth factor required for endothelial health.

A particularly severe cellular response is the formation of crescents within Bowman's space. Crescent formation may be initiated by cytokine-driven proliferation of the parietal cells and possibly to a lesser extent the podocyte. Local breaks in the GBM or Bowman's capsule, mediated by activated leukocytes, are followed by macrophage infiltration, myofibroblast accumulation, and local fibrin deposition (Fig. 16.9). Most evidence suggests that crescent formation is a manifestation of cell-mediated rather than of humoral immune mechanisms.¹³

Glomerular scarring is often associated with proliferation of mesangial cells with loss of both endothelial cells and podocytes by apoptosis. Tubulointerstitial fibrosis also accompanies progressive glomerular disease and correlates with both renal function and prognosis. Proteinuria has been shown to activate tubular

cells and induce toxicity, either directly or by the generation of oxidants (from iron proteins excreted in the urine) or complement activation (which can be shown in proteinuric urine). Tubulointerstitial ischemia may also be involved in the pathogenesis of renal fibrosis as a progressive loss of glomerular and peritubular capillaries can be shown in both experimental models and human disease. Finally, misdirected filtration (i.e., filtration of plasma ultrafiltrate into the peritubular space) as well as the formation of atubular glomeruli may contribute to progressive tubulointerstitial damage in the course of glomerular disease.

A detailed discussion of current mechanisms involved in glomerulosclerosis is presented in Chapter 76.

Specific pathogenic mechanisms in the different patterns of glomerular disease are discussed in the subsequent chapters in this section.

PATHOGENESIS OF SPECIFIC GLOMERULAR SYNDROMES

Minimal Change Disease

MCD is classically a corticosteroid-sensitive nephrotic syndrome in which the only structural abnormality is podocyte swelling and fusion of foot processes by EM (see Chapter 17). The disease is thought to be due to podocyte injury. The induction of CD80 (B7.1) in podocytes has been shown to cause rapid onset of proteinuria in experimental animals,¹⁴ and CD80 has been recently identified in podocytes of patients with MCD. CD80 antigen is also present in the urine of subjects with MCD and correlates with disease activity. The mechanism of CD80 expression is unknown but could be mediated by viral or bacterial antigens or possibly by T-cell cytokines. T cells are activated in subjects with

Figure 16.9 Crescent formation. In early crescent formation, cytokines and growth factors cross the GBM to initiate proliferation of the parietal epithelial cells. Small breaks in the GBM occur secondary to injury from oxidants and proteases from neutrophils and macrophages, thus allowing the macrophage to enter Bowman's space, where it can proliferate. Breaks in Bowman's capsule secondary to the periglomerular inflammation also occur, allowing the entrance of more inflammatory cells as well as fibroblasts. The proliferation of parietal and visceral epithelial cells and macrophages is associated with fibrin deposition, slowly choking the glomerular tuft until filtration becomes impossible. In the late stages, the crescent becomes fibrotic and the glomerulus end stage. Alternatively, in less severe cases, complete restitution of the glomerular tuft can occur.

MCD, and T-cell hybridomas from patients with MCD secrete a factor that provokes heavy proteinuria in rats.¹⁵ Interleukin-13 is expressed by T cells in subjects with MCD, and overexpression of interleukin-13 induces CD80 in podocytes of rats with the development of nephrotic syndrome and histologic changes consistent with MCD. However, CD80 expression in podocytes can occur in the absence of T cells. In addition, proteinuria can be induced in immune-deficient mice by CD34-positive hematopoietic bone marrow cells of patients with MCD and recurrent FSGS but not by their T cells.¹⁶ Thus, the role of T cells in this disorder remains to be clarified.

Focal Segmental Glomerulosclerosis

FSGS is a type of nephrotic syndrome that is often slowly responsive or nonresponsive to corticosteroids; there are no immune deposits, but there is foot process fusion by EM (see Chapter 18). However, the characteristic histologic lesion is of segmental sclerosis. Some cases of FSGS appear to be mediated by a soluble factor that is not yet fully defined. It is also not known if the pathogenesis overlaps with MCD.

A variant of FSGS is collapsing FSGS, in which there is proliferation of the normally quiescent podocyte, leading to collapse of the glomerular tuft, often in association with massive proteinuria. The pathogenesis may be due to production by the podocyte of growth factors (such as vascular endothelial growth factor) or local inhibition of cell cycle proteins that normally maintain the podocyte in a nonproliferative state.¹⁷

Focal sclerosing lesions in the absence of severe proteinuria can also occur in a wide variety of renal lesions besides nephrotic syndrome, including GN, chronic hypertension, and progressive renal disease of any etiology. These lesions are particularly common in African Americans; recent findings suggest that this susceptibility relates to increased frequency of a genetic polymorphism in *MYH9*, a gene coding for a nonmyosin protein in the podocyte that affects podocyte structure and function.¹⁸

Membranous Nephropathy

In membranous nephropathy (MN), immune deposits are localized to the subepithelial space (see Chapter 20). Most experimental studies suggest that deposits are formed *in situ* by binding of antibody to intrinsic or planted antigens on the glomerular epithelial cells. In animal studies (passive Heyman nephritis), the intrinsic antigen (megalin) has been identified. In human studies, neutral endopeptidase has been identified as the antigen in the very rare congenital MN. More recently, Beck and colleagues¹⁹ have identified the 185-kd phospholipase A₂ receptor that is expressed on podocytes as the putative antigen for as many as 70% of cases of idiopathic MN. Some cases of MN may be due to low-avidity immune complexes, which may dissociate and then re-form at the subepithelial space; this may provide a mechanism for some MN due to viruses, such as hepatitis B virus. Podocyte injury is mediated by local complement activation with insertion of C5b-9 into the cell membrane. However, experimental MN (passive Heyman nephritis) can also be induced in rats that are unable to generate C5b-9.²⁰

Membranoproliferative Glomerulonephritis

In MPGN type I, the immune deposits localize both to the mesangium and to the subendothelial space (see Chapter 21). A similar pattern is observed in cryoglobulinemic GN, in which

the immune complexes contain a monoclonal IgM or polyclonal IgM that acts as a rheumatoid factor by binding to the IgG in the immune complex. In both cases, the disease is thought to occur by passive deposition from the circulation. When this pattern is seen in lupus nephritis, it may be facilitated by the binding of nucleosomes to the complexes (nucleosomes are cationic nuclear proteins that can interact with the negatively charged proteins within the glomerulus).

Studies in experimental models suggest that the intraglomerular immune complexes cause local complement activation with the generation of chemotactic factors (including C5a, chemokines, and leukotrienes). Leukocyte adhesion molecules on endothelial cells are upregulated (intracellular adhesion molecule 1) or expressed *de novo* (E- and P-selectins). Proinflammatory cytokines (interleukin-1 and tumor necrosis factor α) are generated locally and augment the inflammatory response. Neutrophils, platelets, and monocytes-macrophages then localize in the glomerulus and release oxidants (particularly hypohalous acids generated by neutrophil myeloperoxidase) and proteases (elastase, cathepsin G, and metalloproteinases) that cause local cellular injury and GBM degradation.

Dense Deposit Disease

In contrast to MPGN type I, immune complexes are absent in glomeruli of patients with DDD. Here, activation appears to derive from spontaneous intraglomerular activation of the alternative pathway of complement, for example, through mutations of the complement regulatory factor H.²¹ In the case of factor H, the location of the mutation within the gene determines whether the disease is manifested as DDD or atypical hemolytic-uremic syndrome.²¹

Mesangial Proliferative Glomerulonephritis

IgA nephropathy, a mesangial proliferative GN, is the most common type of GN (see Chapter 22). Production of an abnormally glycosylated IgA, possibly by a bacterial superantigen²² or aberrant T-cell response, may lead to IgA polymers that deposit in the mesangium; the glomerular capillary wall is relatively spared. Marked proteinuria is not commonly a major feature of the clinical presentation. Mesangial cell injury may be mediated by binding of the IgA-containing immune complexes to Fc α or other IgA receptors on the mesangial cell, resulting in the release of chemokines and growth factors that provokes leukocyte infiltration and mesangial cell proliferation and mesangial matrix production.

Poststreptococcal Glomerulonephritis

PSGN has long been considered the human equivalent of acute serum sickness in rabbits (see Chapter 55). It is thought that nephritogenic strains of group A streptococcus release specific antigens, especially streptococcal pyrogenic exotoxin B, into the circulation, where they bind to antibody and localize to glomeruli. Other antigens may also be involved, including nephritis-associated plasmin receptor, which can activate the alternative pathway of complement and therefore augment the inflammatory response independent of antibody. Activation of complement in the proximity of the endothelium leads to a brisk inflammatory reaction with local endothelial and mesangial cell proliferation and manifestations of the nephritic syndrome. Some deposits ("humps") also form in the subepithelial space and

may represent the translocation of immune complexes across the GBM.

Goodpasture's Disease

Goodpasture's disease (anti-GBM disease) is due to an autoantibody to the $\alpha 3$ chain of type IV collagen present in the GBM and alveolar basement membrane (see Chapter 23).⁸ The autoantibody develops antigens in genetically susceptible individuals because of molecular mimicry between the type IV collagen antigens and certain bacterial antigens.⁸ Binding of antibody results in complement activation with the infiltration of inflammatory cells that causes local capillary wall damage and proteinuria. Crescent formation also commonly occurs and may be mediated by both T cells and macrophages.

ANCA-Associated Vasculitis

A severe form of segmental necrotizing glomerular injury, often in association with crescents, can be observed with various types of vasculitis (see Chapter 24). The two most common types of vasculitis causing this type of injury are Wegener's granulomatosis and microscopic polyangiitis. Both are associated with circulating antibodies against neutrophil cytoplasmic antigens (ANCA); antibodies to proteinase 3 give a cytoplasmic pattern by staining (c-ANCA) in most patients with Wegener's granulomatosis, and antibodies to myeloperoxidase give a paranuclear staining pattern (p-ANCA) in subjects with microscopic polyangiitis. Whereas there is experimental evidence that ANCA are pathogenic by activating neutrophils within the vasculature, pathogenic autoantibodies to lysosome-associated membrane protein 2 (LAMP-2) present in endothelial cells have recently been identified in vasculitis.⁹ LAMP antibodies appear to develop as a consequence of molecular mimicry with various bacteria and viruses and when injected into rats result in crescentic nephritis. The clinical value of measuring LAMP autoantibodies is not yet clear.

Minimal Change Nephrotic Syndrome

Philip D. Mason, Peter F. Hoyer

DEFINITION

Minimal change disease (MCD) is the cause of nephrotic syndrome in about 90% of children younger than 10 years, about 50% to 70% of older children, and 10% to 15% of adults. MCD is defined by the absence of histologic glomerular abnormalities, other than ultrastructural evidence of epithelial cell foot process fusion, in a patient presenting with nephrotic syndrome who is typically corticosteroid responsive. Corticosteroid-sensitive nephrotic syndrome is the term used to describe the disease occurring in children with nephrotic syndrome who respond to corticosteroids but who have not had a renal biopsy to provide the histologic proof of MCD. The presence of nephrotic syndrome is important because similar histologic findings may be seen in patients with proteinuria in the absence of nephrotic syndrome. Such patients may have different conditions with different prognoses and requirements for management.

Whereas MCD is classically associated with normal-appearing glomeruli and corticosteroid responsiveness, MCD appears to overlap with a variety of histologic variants that have a tendency to be less corticosteroid responsive. These conditions include focal segmental glomerulosclerosis (FSGS; see Chapter 18) and IgM nephropathy (see later discussion). It is possible that both MCD and FSGS have similar initial histologic appearances but that FSGS is less corticosteroid responsive and hence develops secondary sclerosing lesions over time. Whether this represents a continuum of the same disease in which some subjects are corticosteroid sensitive and others are not or whether they represent two distinct etiologies remains debated.

ETIOLOGY AND PATHOGENESIS

MCD is the most common cause of nephrotic syndrome in children aged 2 to 12 years. However, it is also relatively common in adults. Many patients have a history of allergy, including atopy, asthma, or eczema (Fig. 17.1). Most cases are idiopathic, but MCD has also been associated with certain cancers, especially Hodgkin's disease, in which it may be the presenting symptom. Finally, MCD has been associated with the use of certain drugs, such as interferon alfa and nonsteroidal anti-inflammatory drugs (NSAIDs) (see Fig. 17.1).

The primary abnormality in MCD is a defect in the glomerular filtration barrier to protein. In normal glomeruli, the barrier to protein filtration is provided by the glomerular basement membrane (GBM) and the slit diaphragm that extends between the podocyte foot processes. Size barriers and charge selectivity of GBM exclude neutral molecules larger than 4 to 4.5 nm from filtration; albumin molecules that are smaller than this are

excluded because they are anionic and are repelled by the negative charge on the epithelial cells and GBM.

In MCD, FSGS, and other causes of nephrotic syndrome, the clearance of proteins becomes markedly enhanced, whereas the filtration of small molecules is actually reduced. Some authorities have attributed the reduction in small molecular clearance to the diffuse foot process fusion, which reduces overall slit diaphragm area and thereby may account for the reduction in the ultrafiltration coefficient (K_f , see Chapter 2) that is typically observed. In contrast, the albuminuria is thought to result from specific areas ("large pores") where the protein escapes into the urine.

Studies in nephrotic syndrome have implicated injury to the podocyte, and particularly the slit diaphragm, as the key factor leading to proteinuria. The importance of the slit diaphragm for nephrosis was first shown with the congenital nephrotic syndrome of the "Finnish type," in which the primary defect is a mutation in nephrin, a key protein in the slit diaphragm. In particular, this nephrotic syndrome can histologically and clinically appear identical to MCD, except that it typically begins shortly after birth and is corticosteroid resistant (see Chapter 19). Since the discovery of the etiology of this nephrotic syndrome, numerous other congenital causes of nephrotic syndrome have been identified that all have in common mutations in genes involved in the slit diaphragm (*NPHS1*, *NPHS2*, *NPHS3*, *WT1*, *LAMB2*, *LMX12*, *ACTN4*, *CD2AP*, *TRPC6*; see Chapter 19).

Evidence for a primary podocyte abnormality contributing to MCD is beginning to emerge. For example, MCD is associated with expression of CD80 (B7.1) on the podocyte, and shed CD80 can be found in the urine of patients with MCD.¹ Experimental studies have shown that CD80 expression by podocytes results in shape change and the development of proteinuria. Reduced levels of dystroglycans (adhesion molecules believed to anchor podocytes to the GBM) have also been reported in MCD but not in FSGS, with normalization after corticosteroid treatment.²

Others have proposed that the permeability defect is due to alterations in the GBM, particularly a loss of negative charge. In this case, the podocyte changes could be secondary to the proteinuria. This would be consistent with observations of preserved foot processes in the early phase of some highly proteinuric states (e.g., recurrent FSGS after renal transplantation) and of podocyte foot process fusion in children with severe hypoalbuminemia, but not proteinuria, dying of kwashiorkor.³

There is also some evidence that there may be a circulating factor responsible for inducing the alteration in the capillary wall. Hemopexin, an acute-phase reactant extracted from human plasma, is capable of inducing proteinuria in rats,⁴ and in one

small study, plasma hemopexin activity was increased in MCD patients in relapse with some evidence of an altered isoform.⁵ Evidence of a circulating factor in humans is also supported by the observation that proteinuria resolved within days after transplantation from a cadaveric donor with MCD.⁶ Evidence for a T-cell abnormality includes the absence of immune deposits, the remarkable sensitivity of the disease to corticosteroids and cyclosporine, the relationship with Hodgkin's disease, and the reports that active measles infection (which depresses cell-mediated immunity) can rapidly induce remission. Studies have shown that T regulatory cells are abnormal in MCD and that there is generalized activation of T cells during active disease.

Some studies have also implicated interleukin (IL)-13 released from T cells in causing the proteinuria, as T-cell production of IL-13 is elevated and overexpression of IL-13 can induce nephrotic syndrome in rats.⁷ Interestingly, the mechanism involved induction of CD80 in the podocyte. IL-13 is also a cytokine associated with allergic states, and MCD can be triggered by vaccination⁸ or exposure to an allergen in sensitive individuals. As a result, patients with identified food allergies have been managed with exclusion diets with reported complete

or partial remissions and with relapse after reintroduction of the offending food. However, even if the relationship is real, it is possible that the allergic events merely trigger relapse, as may infections.

Whereas a T-cell mechanism remains likely, there is also an interesting report in which proteinuria could be induced in experimental animals with use of CD34⁺ stem cells from subjects with MCD.⁹

Finally, an association has been reported with HLA-DR7 (in some ethnic groups), at least in corticosteroid-responsive individuals.

EPIDEMIOLOGY

MCD affects 2 to 7 per 100,000 children per year, with a prevalence of 15 per 100,000, most commonly presenting between 2 and 7 years of age. It is also an important cause of nephrotic syndrome in adults of all ages, although the incidence varies geographically. MCD is reported to be as low as 1 per million in the United Kingdom and up to 27 per million in the United States. It is more common in South Asians and Native Americans but is much rarer in African Americans, in whom nephrotic syndrome is much more likely to be due to FSGS and to be corticosteroid resistant. MCD is also relatively rare in developing countries, such as most countries in Africa and South America (Fig. 17.2).¹⁰⁻¹² Boys are twice as likely to be affected as are girls, but the sex incidence is equal in adolescents and adults. There are data suggesting that MCD has become less common in adults.¹³

CLINICAL MANIFESTATIONS

Patients typically present with edema that develops during days to weeks with fluid retention that often exceeds more than 3% of the body weight. Up to two thirds of initial presentations and relapses follow an infection, most commonly of the upper respiratory tract, but whether these are of causative significance is uncertain.

The clinical signs and symptoms are the same as those for nephrotic syndrome of any cause (see Chapter 15), although nephrotic syndrome is often of very rapid onset, increasing the risk of hypovolemia, particularly in children. Pleural effusions and ascites are common, particularly in children, who may present with abdominal pain, a symptom that may suggest peritonitis or herald hypovolemia. Pericardial effusions may occur infrequently (but rarely cause significant complications), and pulmonary edema is uncommon except after excessive treatment with albumin or with coexisting cardiac disease. Hepatomegaly is frequent in children but may be overlooked in the presence of

Factors Associated with the Onset of Nephrotic Syndrome in Minimal Change Disease	
Drugs	
Nonsteroidal anti-inflammatory drugs (NSAIDs)	
Interferon alfa	
Lithium: rare (usually causes chronic interstitial nephritis)	
Gold: rare (usually causes membranous nephropathy)	
Allergy	
Pollens	
House dust	
Insect stings	
Immunizations	
Malignancy	
Hodgkin's disease	
Mycosis fungoides	
Chronic lymphocytic leukemia: uncommon (usually associated with membranoproliferative glomerulonephritis)	

Figure 17.1 Factors associated with the onset of nephrotic syndrome in minimal change disease.

Frequency of Various Types of Nephrotic Syndrome in Children and Adults from Europe, the United States, and Africa				
Histology	Children	Adults	Zimbabwe	Durban
MCD	76	20	9.2	14
FSGS	8	15	15.1	28
MN	7	40	15.1	41 (35 Hep B)
MPGN	4	7	33.6	9
Misc.	5	18	17.0	5

Figure 17.2 Frequency of various types of nephrotic syndrome (in annual incidence per million population) in children and adults from Europe, the United States, and Africa. MCD, minimal change disease; FSGS, focal and segmental glomerulosclerosis; MN, membranous nephropathy; MPGN, membranoproliferative glomerulosclerosis. (Data from references 10-12.)

ascites. The distribution of edema is gravitational, but facial puffiness is common and genital swelling may be very uncomfortable, especially in men. Gross edema may predispose to ulceration and infection of dependent skin; striae often appear even without corticosteroids, and lacerations or needlestick punctures weep fluid profusely. Edema of the bowel may cause diarrhea, rarely with significant albumin loss from the gut. Other clinical features include white nails, sometimes in bands (Muehrcke's bands) correlating with periods of clinical relapse (see Fig. 15.4). In adults, xanthomas may occasionally result in association with gross hyperlipidemia.

Microscopic hematuria is rare in MCD, and although hypertension is not typical in children, it has been observed at presentation in 30% of 89 adults in one study from the United Kingdom.¹⁴ Higher blood pressure than normal has also been described in 14% to 21% of children, when comparisons are made with appropriate age- and sex-matched blood pressure reference ranges. This usually resolves during remission, especially in children. Hypertension is sometimes associated with expansion of the intravascular volume but may paradoxically be related to hypovolemia and stimulation of the renin-angiotensin system (RAS).

Before the introduction of corticosteroids, the morbidity and mortality of patients with MCD were high because of complications of nephrotic syndrome, particularly infection. Infection continues to be a serious problem, particularly in those presenting late,¹⁵ and 6 of 389 children with MCD described by the International Study of Kidney Disease in Children (ISKDC) in 1984 died of sepsis.¹⁶ Peritonitis remains a major cause of mortality in the developing world, mainly in children. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and other encapsulated bacteria are commonly implicated. Children with frequently relapsing nephrotic syndrome should be immunized against *S. pneumoniae* and *H. influenzae* during remission and given prophylactic oral penicillin in relapse.¹⁷ Peritonitis is rare in adults, who usually have protective antibodies against these bacteria, and prophylactic antibiotics are not indicated.

The risk of thromboembolism is increased in MCD, as in all subjects with nephrotic syndrome (see Chapter 15). Venous thromboembolism may occur in the lower extremities, renal veins, and other sites. Pulmonary embolism may be overlooked in children because of a lack of suspicion, even with pulmonary symptoms, and children may compensate better than adults do. Nephrotic children occasionally have other catastrophic events, such as intracerebral venous or sinus venous thrombosis. Arterial thrombosis is also a rare and feared complication that has been described in children almost exclusively and may result in loss of limbs.

Renal function is generally preserved, but the serum creatinine concentration is sometimes slightly elevated in adults. Acute kidney injury is a complication particularly seen in adults. It may follow hypovolemia, which should be avoided especially during intensive diuretic treatment, but it may also rarely occur in patients who are volume replete (see also Chapter 15).

Secondary MCD may mimic idiopathic MCD and may result from drugs or with cancer. The classic drugs associated with MCD are NSAIDs and particularly fenoprofen. This is an idiosyncratic reaction and is usually associated with chronic NSAID use that has occurred for several weeks or months. Unlike classic MCD, this syndrome is usually associated with massive nephrotic syndrome with impaired renal function, and renal biopsy shows MCD with features of an acute interstitial nephritis with T-cell infiltration. Other causes of secondary MCD, such as the

Figure 17.3 Podocyte foot process fusion in minimal change disease. The epithelial cells (arrows) are completely effaced along the glomerular basement membranes. (Electron micrograph; magnification $\times 6000$.) The normal appearance of epithelial cell foot processes is shown in Figures 1.7 and 1.8 (see Chapter 1).

use of interferon alfa or interferon beta, or MCD observed in Hodgkin's disease, may appear clinically identical to idiopathic MCD.

PATHOLOGY

Classically, MCD is associated with normal-appearing glomeruli by light microscopy and is negative for immunoglobulins and complement by immunofluorescence or other methodologies. Podocyte (epithelial cell) foot process effacement is observed with electron microscopy (Fig. 17.3) and is the only abnormality, but this is a nonspecific finding. The tubulointerstitium will show an absence of inflammation. Hyaline casts obstructing tubules, rare foam cells, and occasionally appearances consistent with acute tubular necrosis may be seen, especially if acute kidney injury is present at the time of biopsy.

Variants

Mild mesangial hypercellularity is an infrequent finding (3% to 5%), and small amounts of mesangial IgG, complement C3, and occasionally IgA may be observed in patients whose clinical course is indistinguishable from classic MCD.

The glomerular tip lesion describes structural segmental changes adjacent to the tubular pole of Bowman's capsule, with protrusion into the tubular lumen. This is observed more commonly in adults than in children. Whether this is a variant of MCD or should be considered a type of FSGS is controversial. Generally considered a benign lesion, it may also be rarely observed in membranoproliferative glomerulonephritis, IgA nephropathy, and renal allografts. The most important reason to recognize the lesion is to prevent a misdiagnosis of a proliferative glomerulonephritis.

The presence of mesangial hypercellularity in MCD may correlate with increased resistance to corticosteroid therapy.¹⁸ Some consider mesangial hypercellularity to be an intermediate step in cases of evolution (progression) of MCD to FSGS (see Chapter 18).

IgM Nephropathy

Some patients presenting with nephrotic syndrome have mesangial deposits of IgM, often with a minor degree of

mesangial hypercellularity. Patients are more likely to have microscopic (and occasionally macroscopic) hematuria and are also less likely to respond to corticosteroids (50% compared with 90% for minimal change nephrotic syndrome).¹⁹ Whether this represents a distinct entity or is part of the spectrum observed with MCD and FSGS remains uncertain (see also Chapter 27).

Focal Segmental Glomerulosclerosis

Some patients who are considered to have MCD by renal biopsy may not respond to corticosteroids and on repeated biopsy are found to have FSGS. Others who initially are responsive to corticosteroids eventually become resistant and are discovered to have FSGS on a subsequent biopsy. This has led some to suggest that MCD and FSGS are part of a spectrum of the same disease process. However, it remains possible that the initial biopsies may have missed the sclerotic lesions of FSGS because they are focal.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of nephrotic syndrome is straightforward, with edema in the presence of heavy proteinuria, usually without microscopic hematuria on urine dipstick testing. Urine microscopy reveals hyaline casts and sometimes lipid casts. There is hypoalbuminemia (<2.5 g/dl) and nephrotic-range proteinuria (>3.5 g/24 h in adults or >1 g/m²/24 h [≈ 40 mg/m²/h] in children) or a protein to creatinine ratio of more than 0.25 g/mmol (>2 mg protein/mg creatinine) on a spot urine sample. Hyperlipidemia is also a common laboratory finding. Hyponatremia and hemoconcentration may be seen, even before treatment. Elevated urea and creatinine concentrations occur more often in adults. Typically, serum IgG levels are low and IgM is increased. Serum complement levels are normal.

In children, corticosteroid-sensitive MCD is usually associated with selective proteinuria of smaller molecules, including albumin and transferrin, but not of larger molecules, such as immunoglobulins and ferritin. A selectivity index is usually derived from the ratio of IgG clearance to albumin clearance:

$$\text{Selectivity index} = \frac{[(\text{IgG})_u (\text{albumin})_s]}{[(\text{IgG})_s (\text{albumin})_u]}$$

where subscript *u* is concentration in urine and *s* is that in serum. If the selectivity index is less than 0.1, the proteinuria is highly selective, and if it is more than 0.2, it is nonselective. This is of limited clinical value because highly selective proteinuria is less common in adult MCD and does not influence the decision to treat with corticosteroids. However, highly selective proteinuria, when it is present, does indicate that MCD is more likely to be the diagnosis, and some argue that such patients should be given a trial of corticosteroids without a renal biopsy, especially if the risk of biopsy complications is high.

In children from the Northern Hemisphere aged 2 to 12 years, renal biopsy is unnecessary unless the patient does not respond to a standard prednisone treatment of 60 mg/m²/day within 4 weeks. In Africa and South America, the prevalence is lower. In this setting, a trial of corticosteroids might depend on how common MCD is in this region and should also take into consideration the higher risk of infections.

In adults, in whom there is a wide differential diagnosis for nephrotic syndrome and corticosteroid responsiveness is less likely, a renal biopsy is required to establish the diagnosis.

On occasion, a renal biopsy may histologically appear like MCD, but there is another cause. In subjects with nephrotic syndrome, this may be due to FSGS in which the sclerotic glomeruli are not sampled. In young children, it could be due to a hereditary nephrotic syndrome resembling MCD (see Chapter 19). Rarely, early membranous nephropathy will have a light microscopic appearance of normal glomeruli, but immunofluorescence will reveal immune deposits. Early amyloidosis may also mimic MCD histologically in the adult. Finally, in non-nephrotic subjects, diseases such as thin basement membrane disease can appear histologically normal but can be diagnosed by demonstration of the thin GBM by electron microscopy.

NATURAL HISTORY

There is a tendency for patients with MCD to run a relapsing-remitting course, and this is more frequent in children. Those presenting younger are more likely to have more relapses and a longer disease course (Fig. 17.4).²⁰ Relapse is common, affecting more than two thirds of children, and nearly 50% will relapse more than four times, usually after corticosteroid cessation or reduction. If relapse occurs during corticosteroid reduction, the patient is described as corticosteroid dependent. Long-term remission can be expected in 75% of initial responders who do not relapse within 6 months; those who do relapse become non-relapsing after an average of 3 years, and 84% are in long-term remission after 10 years.²¹ Indeed, it is reassuring that less than 5% of children with MCD enter adulthood still having relapses, although the younger the age at the onset of the first attack, the longer the child is likely to continue having relapses.^{20,22} In general, increasing time since last relapse reduces the risk of further relapse, but adults will occasionally have a relapse after an interval of 10 years or more.

MCD does not progress to renal failure. However, a number of adult patients, but fewer children, with an initial diagnosis of MCD are found to have FSGS on subsequent biopsies, and they may develop progressive renal failure. It is still unclear whether the focal nature of the disease caused the correct diagnosis to be missed on the initial biopsy or whether evolution from MCD to FSGS occurs in some individuals.

Figure 17.4 Long-term outcome in childhood-onset minimal change disease. The duration of disease is inversely related to the age at presentation. (Modified from reference 20.)

Nephrotic Syndrome: Definitions		
Term	NS Definitions	
	Adult	Pediatric ^{14, 15}
Relapse	Proteinuria ≥ 35 g day ⁻¹ occurring after complete remission has been obtained for >1 month	Albu-stix 3+ or proteinuria >40 mgm ⁻² h ⁻¹ occurring on 3 days within 1 week
Frequently relapsing Complete remission	2+ relapses within 6 months Reduction of proteinuria to ≤ 0.20 g day ⁻¹ and serum albumin >35 g l ⁻¹	2+ relapses within 6 months <4 mg m ⁻² h ⁻¹ on at least 3 occasions within 7 days serum albumin >35 g l ⁻¹
Partial remission	Reduction of proteinuria to between 0.21 g day ⁻¹ and 3.4 g day ⁻¹ \pm decrease in proteinuria of $\geq 50\%$ from baseline	Disappearance of edema. Increase in serum albumin >35 g l ⁻¹ and persisting proteinuria >4 mgm ⁻² h ⁻¹ or >100 mg m ⁻² day ⁻¹
Steroid-resistant	Persistence of proteinuria despite prednisone therapy 1 mg kg ⁻¹ day ⁻¹ \times 4 months	Persistence of proteinuria despite prednisone therapy 60 mg m ⁻² \times 4 weeks ^a
Steroid-dependent— NS recurs when stop or decrease treatment	Two consecutive relapses occurring during therapy or within 14 days of completing steroid therapy ¹⁶	Two relapses of proteinuria within 14 days after stopping or during alternate-day steroid therapy

The definitions were generated by a consensus of the International Society for Kidney Diseases in Children and the German Pediatric Nephrology Society. NS, nephrotic syndrome. ^aOr persistence of proteinuria despite prednisone therapy 60 mg m⁻² \times 4 weeks and three methylprednisolone pulses. (Data from reference 23.)

TREATMENT

Definitions That Guide Treatment

Figure 17.5 provides key definitions related to the clinical response of MCD to treatment that are used to guide therapy.²³ For example, subjects who relapse more than three times within a year are considered frequently relapsing, whereas subjects who respond to corticosteroids but relapse before discontinuation are considered corticosteroid dependent. Subjects who remain proteinuric despite a course of corticosteroids are considered corticosteroid resistant. Stratification of patients into their category can help in management (see later discussion).

Initial Treatment of Minimal Change Disease

Initial management of MCD includes standard management of nephrotic syndrome as discussed in Chapter 15, including low-sodium diet to control edema. Bed rest should be avoided because of the increased risk for thrombosis. Diuretics are infrequently used in children as they may cause further volume depletion, but they are often used to control extracellular volume in adults, in whom hypovolemia before treatment is less common. In those who remain with prolonged nephrotic syndrome, treatment of hyperlipidemia with statins and prophylaxis for thrombosis should be considered.

Childhood Minimal Change Disease

Treatment of First Episode

Corticosteroids are the initial treatment of choice (see algorithm, Fig. 17.6). According to the ISKDC, children (aged 2 to 12 years) with a first episode of nephrotic syndrome should be treated with oral prednisone (or prednisolone) 60 mg/m²/day (maximum dose 80 mg/day) given in three divided doses (calculated on the basis of estimated dry weight). With this regimen, about 75% respond within 2 weeks, and almost all who are corticosteroid sensitive

respond within 4 weeks (Fig. 17.7).^{25,26} Those who do not respond within the period are regarded as nonresponders.¹⁹

Whereas the ISKDC recommendations proposed that the daily dose be continued for a total of 4 weeks, later studies argue for a duration of 6 weeks.²⁷ This daily dose should be followed by an alternate-day dose of 40 mg/m²/48 h for an additional 4 weeks (ISKDC) or 6 weeks (recent data).²⁸ A meta-analysis of trials has demonstrated that extending the duration of corticosteroid treatment to at least 3 months reduces the 1- to 2-year risk of relapse (Fig. 17.8).²⁹

The German Society for Pediatric Nephrology (Arbeitsgemeinschaft für Pädiatrische Nephrologie) recommends stopping corticosteroid treatment for the first episode after 12 weeks; others recommend tapering (e.g., reducing every 2 weeks by 15 mg/m² on alternate days). Although these two regimens have never been compared, we do not recommend tapering because of concerns of chronic corticosteroid use on growth.

Treatment of Relapses

The urine should be tested daily (usually by a parent) during and after treatment. The rationale is that relapses should be treated on the basis of proteinuria (usually requiring at least three or more positive dipstick measurements for 3 consecutive days) to initiate a further course of corticosteroids. The aim is to treat relapse early to avoid nephrosis-associated complications. The intensity of corticosteroid treatment for relapses has not been shown to have an impact on the probability of further relapses.

Our recommendation is oral prednisone 60 mg/m²/day (maximum dose 80 mg/day) given daily in three divided doses until the urine is protein free for 3 days, followed by a course of alternate day prednisone 40 mg/m²/48 h for 4 weeks, then stop. An alternative recommendation is to taper the alternate dose during weeks to months to define a relapse threshold. However, the acceptability of this approach depends on the corticosteroid threshold, and there is a risk of more corticosteroid toxicity with prolonged tapering.

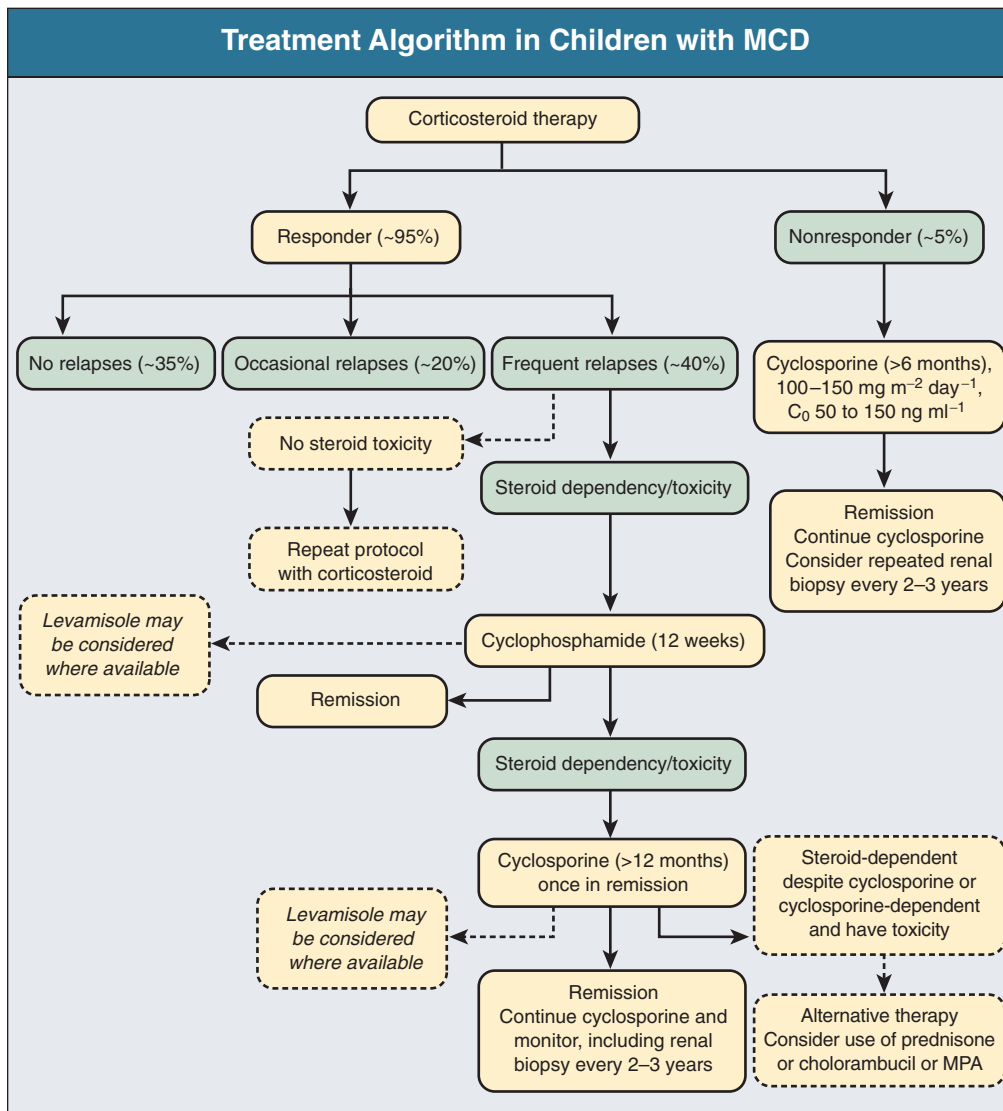

Figure 17.6 Algorithm for treatment of childhood minimal change disease (minimal change nephrotic syndrome). For definitions, see Figure 17.5. The patient or parents should be involved in the decision after the potential side effects of the second-line treatment are considered. In the rare patient who is a nonresponder to standard corticosteroid therapy and by definition corticosteroid resistant, a trial with cyclosporine may be considered.

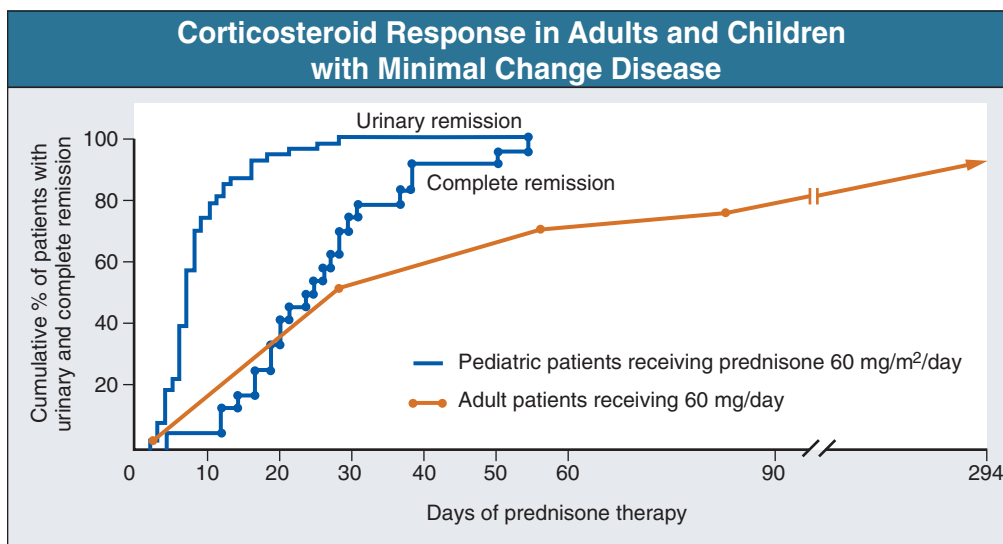

Figure 17.7 Corticosteroid response in adults and children with minimal change disease. Adults with the nephrotic syndrome and MCD take longer to respond than children do and are less likely to remit. The orange line shows the cumulative percentage of adults with complete remission (i.e., reduction of proteinuria ≤ 0.2 g/day and a serum albumin concentration >35 g/l). The blue lines show the cumulative percentage of pediatric patients with urinary remission and with complete remission. Urinary remission is defined by urine on dipstick negative or trace or proteinuria less than 4 mg/m²/day on at least 3 days; the definition of complete remission requires in addition to that a serum albumin concentration above 3.5 g/dl. (Redrawn from data from references 25 and 26.)

Figure 17.8 Duration of corticosteroid therapy for initial treatment of childhood minimal change disease. A Cochrane meta-analysis of studies supports a 12-week or longer course of corticosteroid therapy compared with 2 months in the first episode of corticosteroid-sensitive nephrotic syndrome to induce remission. The summary of studies suggests a 30% better remission rate in those subjects receiving 3 months or more of therapy. (From reference 29.)

Frequently Relapsing and Corticosteroid-Dependent Nephrotic Syndrome

For both frequently relapsing and corticosteroid-dependent nephrotic syndrome, second-line therapy is required. The second-line drugs most commonly used to avoid corticosteroid toxicity are alkylating agents (cyclophosphamide and chlorambucil), levamisole, and cyclosporine. The decision to use second-line therapy for chronically relapsing patients will depend on how quickly corticosteroid-induced remission occurs and how corticosteroids are tolerated. However, corticosteroid dependency is a clear indication for second-line treatment, which should be started before severe corticosteroid toxicity is apparent. The patient or parents usually are involved in the decision after the potential side effects of the second-line treatment are considered.

The alkylating agent cyclophosphamide is the recommended first choice of second-line therapy. Oral cyclophosphamide (2 to 2.5 mg/kg/day) is given for 12 weeks, on the basis of a study suggesting a lower 2-year remission rate compared with an 8-week course,³⁰ although these results have not been supported by all published data.²⁴ Cyclophosphamide can be associated with serious side effects (initially infection and alopecia and subsequently sterility,³¹ hemorrhagic cystitis, bladder cancer, and hematologic malignant neoplasia). However, if therapy is limited to 12 weeks of treatment with 2 mg/kg/day or a total dose of 200 mg/kg body weight, the risks of these complications are low.

Although cyclophosphamide is often effective, it is less effective in children younger than 5.5 years in terms of duration of remission³² (Fig. 17.9), so that this therapy in the very young has been questioned.³³ However, we believe that the benefit of long-term remission, even if the probability is low, justifies the recommendation to use this drug before the alternatives. Chlorambucil (0.2 mg/kg/day) for 2 months appears to be similar to cyclophosphamide in efficacy but has a greater frequency of adverse effects, including seizures, and therefore is not preferable.³⁴

Figure 17.9 Response to cyclophosphamide in corticosteroid-relapsing nephrotic syndrome is dependent on age. Sustained remission is higher in children older than 5.5 years (solid line) compared with those younger (dotted line). (From reference 32.)

In general, frequent relapsers tend to respond better than corticosteroid-dependent children do. Second courses of alkylating agents are not recommended as cumulative toxicity occurs. During treatment with cyclophosphamide or chlorambucil, blood counts should be checked weekly and dose reductions made if necessary. Primary varicella infection carries a particular risk for nonimmune children receiving immunosuppressive therapy, and these children should receive hyperimmune immunoglobulin and probably an anti-herpes agent such as

valacyclovir if there is an unavoidable contact with active chickenpox or shingles infection.

An alternative medication to alkylating agents is cyclosporine. Cyclosporine (up to 150 mg/m² or 3 to 4 mg/kg/day with whole-blood trough levels of 50 to 150 ng/ml) is usually effective in children with both corticosteroid-dependent and frequently relapsing nephrotic syndrome.³² However, relapse is almost invariable within 3 months of stopping treatment, and unfortunately, reintroduction of cyclosporine is often less effective once it has been interrupted. Therefore, cyclosporine is often used as long-term therapy.

If there is no response, increasing the dose of cyclosporine is sometimes effective, but there is a risk of cyclosporine nephrotoxicity even with low-dose regimens, and careful monitoring of blood levels, glomerular filtration rate (GFR), and blood pressure is required. The aim of therapy is to maintain remission without corticosteroids until the underlying disease remits. The optimal duration of cyclosporine therapy is not established, but early withdrawal is discouraged for children. Besides careful monitoring of renal function, kidney biopsies every 2 to 3 years are recommended to ensure safety of the therapy. Although cyclosporine-associated nephrotoxicity during long-term treatment has been reported, one study with careful follow-up suggested that whereas an initial drop in GFR was seen, no further deterioration occurred during the subsequent 5 to 10 years. More long-term studies are needed.

Cyclosporine is also an option in children with corticosteroid-resistant nephrotic syndrome, that is, those not responding to a standard corticosteroid treatment within 4 weeks (see Fig. 17.6).

Levamisole, an anthelmintic drug, has also been used successfully as a nontoxic alternative to corticosteroids (2.5 mg/kg on alternate days for 3 months),^{35,36} but most patients relapse within 3 months of stopping the drug. It is used in the United States, Japan, and the United Kingdom, although it has been withdrawn from the rest of Europe. A clinical trial using levamisole in MCD is ongoing and may provide better insight if there is utility in this disease.

Azathioprine has no proven role in the management of children with MCD and was ineffective in a randomized trial.

Newer Agents

Patients with corticosteroid-sensitive nephrotic syndrome not responding to the established treatments are increasingly being tried on newer agents, including tacrolimus and mycophenolate mofetil (MMF). Tacrolimus is effective but does not have any advantages over cyclosporine. MMF is not nephrotoxic, and despite uncontrolled reports of benefit, a small randomized control trial suggested that the relapse under treatment might be inferior to cyclosporine, but more studies are needed before use of MMF can be recommended.

There have been recent case reports of a dramatic response of patients with childhood nephrotic syndrome to the anti-CD20 monoclonal antibody rituximab, which depletes B cells. The mechanism of the therapeutic effect is not known. In the largest reported multicenter series, 22 young patients (6 to 22 years) with severe corticosteroid- or cyclosporine-dependent nephrotic syndrome underwent remission after rituximab treatment, with one or more immunosuppressive drugs withdrawn in 85% of cases. Relapses occurred with reappearance of B cells. However, 45% reported adverse effects, including one death due to respiratory infection.³⁷ Careful indications and safety measures must be established before this therapy can be recommended.

Adult Minimal Change Disease

There are limited studies comparing different corticosteroid regimens in adults with MCD. As such, conventional treatment recommendations are extrapolated from successful approaches in children, although often with use of slightly lower doses of oral prednisolone (1 mg/kg/day, up to a maximum of 80 mg/day) (Fig. 17.10). There is no good evidence that alternate-day corticosteroids offer any clinical advantages over daily dosing.

Response is often delayed in comparison with children, and 25% fail to remit after 3 to 4 months (see Fig. 17.7).^{14,25,38} The reasons for this are unclear. It has been suggested that many adults are often given a smaller dose of corticosteroids, or it may be that a greater proportion of adults have FSGS, missed on the original biopsy, which is more likely to be corticosteroid resistant.

The dose of prednisone should be reduced to a half-dose 1 week after remission (the absence of protein on urine dipstick testing) and continued for 4 to 6 more weeks, followed by tapering of the corticosteroids during an additional 4 to 6 weeks, aiming, as in children, for a total initial corticosteroid course of at least 3 months (although this principle is not evidence based).

Frequently Relapsing and Corticosteroid-Dependent Nephrotic Syndrome

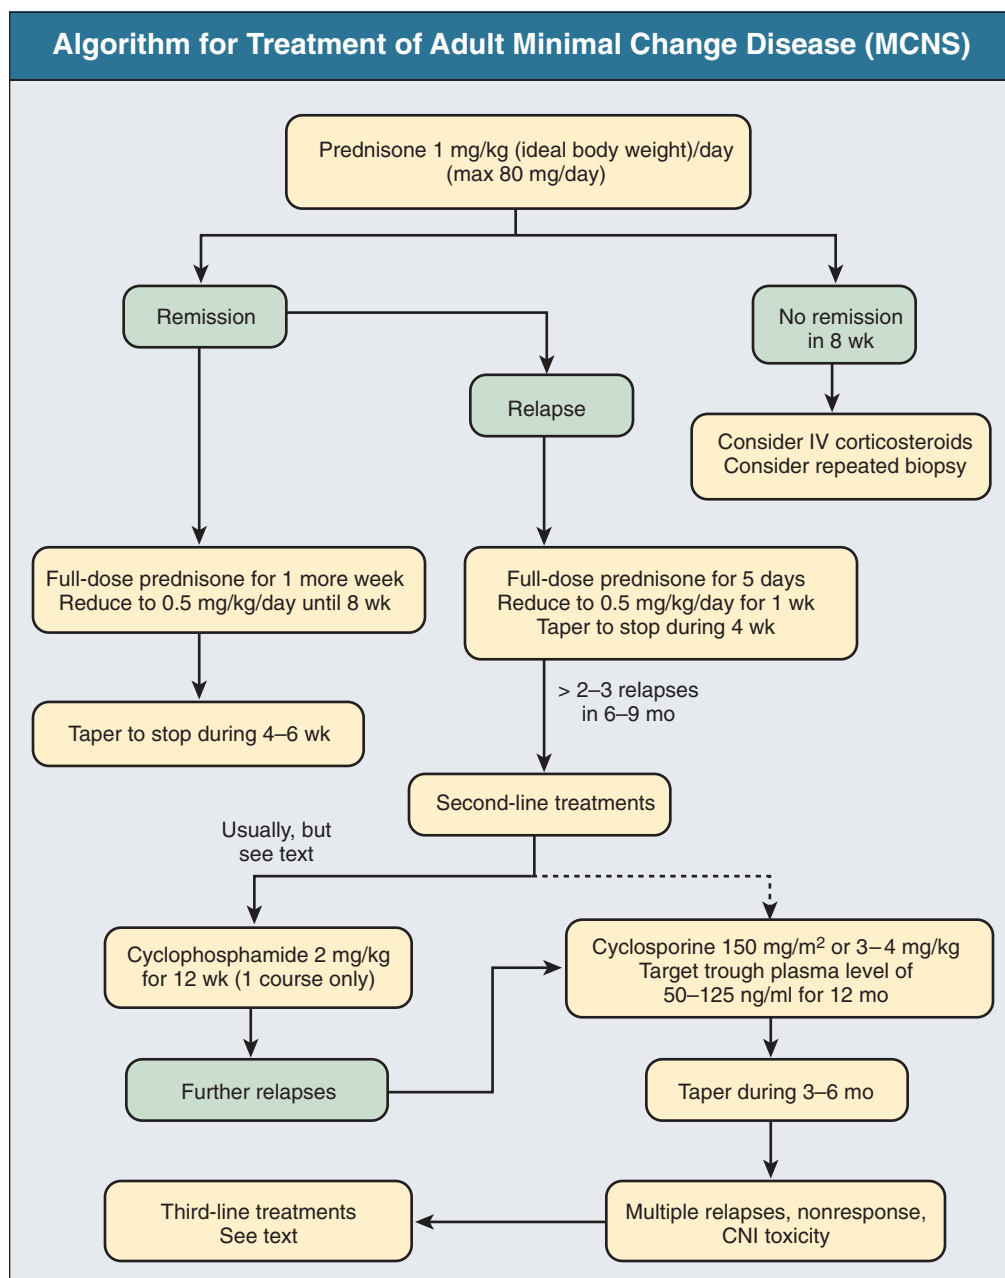

Adults relapse less often than children (30% to 50%). Like children, some adults have transient non-nephrotic relapses. Treatment, initially a repeated course of corticosteroids, should await definitive evidence of relapse with more than 5 consecutive days of proteinuria (>2+ on urine dipstick testing) and a significant weight gain or the development of edema. Frequently relapsing and corticosteroid-dependent patients should be treated with a 12-week course of oral cyclophosphamide, which induces a permanent remission more often in adults than in children (75% and 66% at 2 and 5 years, respectively).¹³ Although there are no satisfactory studies comparing 8- and 12-week courses in adults, the 12-week course is logical on the basis of the pediatric experience. If this treatment is selected, the opportunity for banking sperm or retrieval of eggs should be considered before treatment.

For patients who relapse after cyclophosphamide treatment, cyclosporine (4 to 6 mg/kg/day, aiming for trough whole-blood levels of 50 to 150 ng/ml for at least 12 months) is also effective, but relapse usually follows dose reduction or withdrawal. It is worth considering as a short- to medium-term management strategy because there is evidence that remission eventually occurs in 50% to 75% of patients even without treatment.¹³ However, careful monitoring is required because nephrotoxicity is common after more than 1 year of treatment.³⁹ Some nephrologists prefer to try cyclosporine before cyclophosphamide, especially in younger adults. Tacrolimus appears to be similarly effective. Several uncontrolled reports suggest that MMF and rituximab may also have a place in management of corticosteroid- and cyclosporine-dependent patients,⁴⁰⁻⁴² but more data are needed before these could be widely recommended.

Minimal Change Disease with Non-nephrotic Proteinuria

In subjects with well-documented MCD who have the rare relapse in which the proteinuria is non-nephrotic, treatment does not require corticosteroids but rather can include

Figure 17.10 Algorithm for treatment of adult minimal change disease (minimal change nephrotic syndrome). CNI, calcineurin inhibitor.

angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy. If there is any question as to diagnosis, repeated biopsy may be indicated because other conditions can mimic MCD (see differential diagnosis section).

Treatment of Secondary Minimal Change Disease

MCD secondary to NSAIDs requires discontinuation of the offending medication. Many subjects are treated with a course of corticosteroids for either MCD (higher dose) or for acute interstitial nephritis (see Chapter 60), but evidence that these treatments provide benefit is uncertain.

Secondary MCD from Hodgkin's disease usually responds to treatment of the lymphoma. Some subjects will also be treated with a regimen for MCD as an adjunctive treatment in addition to the chemotherapy directed at the tumor.

Primary and Secondary (Non-Genetic) Causes of Focal and Segmental Glomerulosclerosis

Gerald B. Appel, Vivette D. D'Agati

DEFINITION

Focal segmental glomerulosclerosis (FSGS), a histologic pattern of glomerular injury, defines a number of clinicopathologic syndromes that may be primary (idiopathic) or secondary to diverse etiologies (see also Chapter 19).¹⁻⁴ Early in the disease process, the pattern of glomerulosclerosis is focal, involving a minority of glomeruli, and segmental, involving a portion of the glomerular tuft.^{4,5} Notably, alterations of podocyte cytoarchitecture identified by electron microscopy are relatively diffuse, underscoring the pathogenetic importance of podocyte injury. As the disease progresses, more diffuse and global glomerulosclerosis evolves. Although FSGS accounts for only a small percentage of cases of idiopathic nephrotic syndrome in children, it represents as many as 35% of cases in adults.¹ It is a major cause of progressive renal disease and end-stage renal disease (ESRD) in certain populations.⁶

Diverse pathogenetic mechanisms have been identified and often are manifested as particular histologic subtypes of disease. Through podocyte depletion or dysregulated proliferation, structural deterioration of the glomerular tuft leads to FSGS as a final common pathway.⁵ Although primary (idiopathic) FSGS is potentially treatable and curable in many patients, the optimal type and duration of immunosuppressive therapy as well as adjunctive therapy remain controversial. For secondary FSGS, effective therapies exist to slow or to modify the disease course (see Chapter 76).

ETIOLOGY AND PATHOGENESIS

FSGS represents a common phenotypic expression of diverse clinicopathologic syndromes with distinct etiologies (Fig. 18.1). Causes are as varied as genetic mutations in podocyte proteins (see Chapter 19), circulating permeability factors, viral infections, drug toxicities, maladaptive responses to reduced number of functioning nephrons, and hemodynamic stress placed on an initially normal nephron population. In all these forms of FSGS, injury directed to or inherent within the podocyte is a central pathogenetic mediator.^{2,7,8} These injuries promote altered cell signaling, reorganization of the actin cytoskeleton, and resulting foot process effacement. Critical levels of injury cause podocyte depletion through detachment or apoptosis. Stress placed on the remaining podocytes may lead to local propagation of damage (see also Chapter 75). Injury to podocytes may spread to adjacent podocytes by reduction in supportive factors (such as nephrin signaling) or increased toxic factors (such as angiotensin II [ang II] or mechanical strain on remnant podocytes).⁹ Cell-to-cell spread of podocyte injury until the entire glomerular lobule is captured

could explain the characteristic segmental nature of the sclerosing lesions.

Minimal Change Disease Versus Focal Segmental Glomerulosclerosis

By definition, the etiology of idiopathic or primary FSGS is unknown. Clinical data in some patients support etiologic factors similar to those operant in minimal change disease (MCD; see Chapter 17).¹ Some corticosteroid-responsive FSGS patients who exhibit MCD on initial biopsy subsequently relapse and display FSGS on repeated biopsy. In some, this may simply represent a sampling error in the initial biopsy. In others with well-documented repeated relapses of nephrotic syndrome and multiple biopsies over years, FSGS truly appears to have evolved from an initial MCD pattern. The relatedness of these two diseases is further supported by the observation that pathologic changes in the nonsclerotic glomeruli of idiopathic FSGS resemble glomeruli of MCD.⁵ In addition, sequential biopsies of recurrent FSGS in the allograft have shown that it passes through an early stage that mimics MCD.¹⁰ Thus, the spectrum of MCD and FSGS is often considered together under the rubric of podocytopathies. Recent studies suggest that FSGS and MCD may be distinguished based on the finding of elevated CD80 protein in the urine of corticosteroid sensitive MCD; further studies are necessary to confirm these findings.

As in MCD, in FSGS there is evidence that loss of the glomerular capillary wall charge barrier allows negatively charged albumin to leak into Bowman's space. The alterations in glomerular capillary wall permeability may occur in response to circulating humoral mechanisms that promote foot process effacement. Circulating permeability factors that enhance *in vitro* permeability of glomeruli to albumin have been found in the plasma of some FSGS patients.¹¹ The presence of such permeability factors has been used to predict the recurrence of FSGS in transplanted FSGS patients.¹¹ Some FSGS patients with recurrence of nephrotic syndrome after transplantation achieve remissions of nephrotic syndrome after plasma exchange or use of a protein A adsorption column, supporting the role of a circulating factor (see also Chapter 104).^{12,13} A candidate protein for the permeability factor is cardiotrophin-like cytokine 1 (CLC1), a member of the IL-6 family of interleukins.¹⁴ Receptors for this cytokine are present on podocytes and are upregulated in human recurrent FSGS.¹⁴ The origin of the factor may be CD34⁺ stem cells.¹⁵ Induction of T regulatory cells attenuates the proteinuria in experimental FSGS, suggesting the capacity to block or to suppress the pathogenic cells.¹⁶

Etiologic Classification of Focal Segmental Glomerulosclerosis	
Primary (Idiopathic) FSGS	
Probably mediated by circulating/permeability factor(s)	
Secondary FSGS	
1. Familial/Genetic	<ul style="list-style-type: none"> Mutations in nephrin Mutations in podocin Mutations in α-actinin 4 Mutations in transient receptor potential cation 6 channel (TRPC6) Mutations in WT1 Mutations in informin-2 Mutations in phospholipase C ϵ1
2. Virus Associated	<ul style="list-style-type: none"> HIV-1 ("HIV-associated nephropathy") Parvovirus B19 SV40 CMV
3. Drug Induced	<ul style="list-style-type: none"> Heroin ("heroin-nephropathy") Interferon Lithium Pamidronate Sirolimus
4. Mediated by Adaptive Structural-Functional Responses (Postadaptive)	<ul style="list-style-type: none"> Reduced renal mass <ul style="list-style-type: none"> Oligomeganephronia Very low birth weight Unilateral renal agenesis Renal dysplasia Reflux nephropathy Sequela to cortical necrosis Surgical renal ablation Chronic allograft nephropathy Any advanced renal disease with reduction in functioning nephrons Initially normal renal mass <ul style="list-style-type: none"> Hypertension Atheroemboli or other acute vaso-occlusive processes Obesity Increased lean body mass Anabolic steroids Cyanotic congenital heart disease Sickle cell anemia

Figure 18.1 Etiologic classification of focal segmental glomerulosclerosis (FSGS). WT, Wilms' tumor; HIV, human immunodeficiency virus; CMV, cytomegalovirus.

Whereas there are similarities between MCD and FSGS, the proteinuria in FSGS is often less selective, implying leakage of higher molecular weight macromolecules through "larger pores" in the glomerular basement membrane (GBM). In some toxin-induced animal models of FSGS, such as puromycin or doxorubicin (Adriamycin) nephrosis, nonselective proteinuria develops in conjunction with detachment of the visceral epithelial foot processes from the GBM. Rats injected with sera from patients with idiopathic collapsing FSGS developed proteinuria, glomerular tuft retraction, and podocyte damage, changes that were not seen in rats injected with sera from patients with other FSGS variants or normal controls.¹⁷ The damage was lessened by removal of IgG from the FSGS sera.

Glomerular hypertrophy (or glomerulomegaly) may identify children with MCD at risk for development of FSGS. In early idiopathic FSGS and in many secondary forms of FSGS, such as obesity-related focal sclerosis, there is initially glomerular hypertrophy and a high glomerular filtration rate (GFR), supporting roles for hyperfiltration and increased intracapillary glomerular pressures as mediators of FSGS.¹⁸ Similarly, in secondary forms of FSGS with reduced nephron numbers, maladaptive hemodynamic alterations may be associated with glomerular hyperfiltration and increased intraglomerular capillary pressures. Other factors, such as intraglomerular coagulation and abnormalities of lipid metabolism, may contribute to glomerulosclerosis in these patients (see Chapter 75).

Genetic Variants of Focal Segmental Glomerulosclerosis

Genetic and familial forms of FSGS are covered in detail in Chapter 19. Many cases of apparently primary FSGS may harbor unidentified mutations or polymorphisms in podocyte genes that go unrecognized because of lack of genetic testing and the absence of a heralding presentation with young-onset corticosteroid-resistant disease or familial inheritance. In primary FSGS, a genetic predisposition may underlie the susceptibility to a "second hit," whereby viral factors or other immune stimuli lead to the initiation of disease. Mutations in podocyte genes may also render a patient more susceptible to FSGS induced by such secondary causes as obesity, systemic hypertension, and infectious agents, allowing multifactorial podocyte stress. For example, mutations in myosin heavy chain 9 (*MYH9*) have been identified as a major risk factor for FSGS in patients of African ancestry.¹⁹ Recent genetic mining of populations at risk for FSGS has identified *APOL1* gene, rather than *MYH9*, as the major risk gene for FSGS and chronic hypertensive arterionephrosclerosis among patients of African descent.^{19a} *APOL1* encodes for apolipoprotein L-1. The gene is located along the same stretch of chromosome 22 and is in linkage disequilibrium with *MYH9*. G1 and G2 mutations in *APOL1* are protective against infection by *Trypanosoma brucei*, the parasite spread in Africa by tsetse flies. Just as the gene for sickle cell disease conferred selective advantage against malaria, this appears to be an analogous situation where a genetic mutation became prevalent in a population because it was protective against an infectious pathogen, although it could predispose the host to other intrinsic disease. It remains unclear how sequence variations in *APOL1* mechanistically cause glomerulosclerosis.

Viral Induction of Focal Segmental Glomerulosclerosis

Although a number of studies have noted a relationship between prior viral infection with parvovirus or other viruses and FSGS, in particular collapsing FSGS, the data have been far from consistent.²⁰ By contrast, the role of human immunodeficiency virus (HIV) infection in the pathogenesis is well established (see Chapter 56).

Drug-Induced Focal Segmental Glomerulosclerosis

A number of drugs and medications have been associated with the FSGS phenotype, including heroin, lithium, pamidronate, sirolimus, and interferon alpha, beta or gamma (see Fig. 18.1).^{20a} The abuse of heroin has been associated with the nephrotic syndrome and an FSGS pattern on biopsy, although its incidence

is decreasing in the modern era.²¹ Pamidronate, a bisphosphonate used to prevent bone disease in myeloma and metastatic tumors, has been associated with both collapsing FSGS and MCD.²² Stabilization of renal function and resolution of nephrotic syndrome may follow withdrawal of, for example, interferons, heroin or pamidronate. Longterm anabolic steroid abuse among bodybuilders has been associated with the development of FSGS. Many of these individuals also consume high protein diets and other potentially injurious supplements, including growth hormone. Mechanisms of glomerular injury include potential direct toxic effects of anabolic steroids on glomerular cells and adaptive responses to elevated lean body mass.^{22a}

Structural Maladaptation Leading to Focal Segmental Glomerulosclerosis

Many secondary forms of FSGS are mediated by adaptive structural-functional responses.^{1,7} These postadaptive forms include cases with congenital reduction in the number of functioning nephrons and acquired reduction of nephron numbers, whereas other secondary forms are associated with hemodynamic stress placed on an initially normal nephron population (see Fig. 18.1). Secondary FSGS resembling obesity-related glomerulopathy has been reported in nonobese, highly muscular patients with elevated body mass index due to bodybuilding.²³ Low birth weight associated with prematurity and reduced nephron endowment may also lead to secondary FSGS with glomerular hypertrophy in adolescence or adulthood.²⁴ Biopsy specimens with secondary postadaptive FSGS typically show glomerulomegaly and perihilar lesions of segmental sclerosis and hyalinosis. These conditions resemble experimental models of renal ablation in which the surgical reduction in renal mass causes functional hypertrophy of remnant nephrons with increased glomerular plasma flows and pressures. Whereas these changes are initially “adaptive,” the resultant hyperfiltration and increased glomerular pressure become “maladaptive” and serve as mechanisms for progressive glomerular damage.^{7,8}

Pathogenesis of Progressive Renal Failure in Focal Segmental Glomerulosclerosis

Although much attention has been focused on the pathogenetic basis for proteinuria in FSGS, it is clear that the segmental and eventual global glomerulosclerosis in association with interstitial fibrosis and tubular atrophy underlie the progression to renal failure. The etiology of glomerulosclerosis and its progressive nature are discussed in Chapter 75. Podocytes in some forms of FSGS, such as the collapsing variant, display a dysregulated phenotype with dedifferentiation, proliferation, and apoptosis.²⁵ Such biopsy samples have altered podocyte expression of cell cycle-related proteins.²⁶ In renal biopsy specimens of patients with FSGS, the expression levels of transforming growth factor (TGF) β 1, thrombospondin 1, and TGF- β 2 receptor proteins and mRNAs are all increased, as are podocyte markers of the phosphorylated Smad2/Smad3 signaling pathway.²⁷ Thus, pathways that promote podocyte depletion and overproduction of extracellular matrix converge to produce a sclerosing phenotype.

EPIDEMIOLOGY

Studies of patients who have had a kidney biopsy show an increasing prevalence of FSGS in both adults and children in a number

of different countries on different continents.²⁸ In some countries, such as Brazil, FSGS is currently the most common primary renal disease.²⁹ An analysis of the prevalence of ESRD in the United States caused by FSGS during a 21-year period shows an increase from 0.2% in 1980 to 2.3% in 2000.⁶ Although some of this change in prevalence may relate to changes in biopsy practice or disease classification, it is likely that there is a real increase in the frequency of FSGS.

Primary FSGS is slightly more common in males than in females, and the incidence in both children and adults is higher in blacks than in Caucasians.¹ In the United States, FSGS is the most common cause of idiopathic nephrotic syndrome in adult African Americans.⁶ African Americans had a fourfold greater risk of ESRD from FSGS than Caucasians did. Nevertheless, even in an almost entirely Caucasian U.S. population, a clear major increase in the incidence of FSGS has been documented during a 20-year period in some but not all countries.^{30,30a} The incidence of ESRD due to FSGS in males of all races is 1.5 to 2 times higher than in females. In the United States, idiopathic FSGS is the most common primary glomerular disease detected on renal biopsy that leads to ESRD in all races.⁶

CLINICAL MANIFESTATIONS

Most patients with idiopathic FSGS present with either asymptomatic proteinuria or full nephrotic syndrome.¹⁻³ In children, 10% to 30% of patients with asymptomatic proteinuria are most commonly detected on routine checkups and sports physical examinations; in adults, asymptomatic detection occurs at military induction examinations, obstetric checkups, and insurance or employment physical examinations. The incidence of nephrotic-range proteinuria at onset in children is 70% to 90%, whereas only 50% to 70% of adults with FSGS present with nephrotic syndrome. Edema is, by far, the most common manifestation of FSGS. Secondary forms of FSGS associated with hyperfiltration, such as remnant kidney and obesity-related glomerulopathy, typically have lower levels of proteinuria, and many such patients have subnephrotic proteinuria and a normal serum albumin concentration.^{18,23}

Hypertension is found in 30% to 50% of children and adults with FSGS at the time of diagnosis. Microscopic hematuria is found in 25% to 75% of these patients, and a decreased GFR is noted at presentation in 20% to 30%.¹⁻³ Daily urinary protein excretion ranges from less than 1 to more than 30 g/day. Proteinuria is typically nonselective. Complement levels and other serologic test results are normal. Occasional patients will have glycosuria, aminoaciduria, phosphaturia, or a concentrating defect indicating functional tubular damage as well as glomerular injury.

When patients with the glomerular tip lesion were compared with cases of MCD and FSGS not otherwise specified (NOS), their clinical features were more similar to those of adults with MCD.³¹ Those with tip lesion typically manifested abrupt clinical onset of full nephrotic syndrome (almost 90%), more severe proteinuria, and less chronic tubulointerstitial disease. These patients had a shorter time from onset of clinical disease to renal biopsy, suggesting that tip lesion is an earlier stage in the development of FSGS. The cellular variant also presents with greater proteinuria and incidence of nephrotic syndrome than FSGS NOS does. Patients with the collapsing variant of FSGS often present with greater proteinuria, more full-blown nephrotic syndrome, and lower GFR compared with those with FSGS NOS.^{32,33}

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Before biopsy, patients with FSGS may be confused with any patient who has glomerular disease or nephrotic syndrome with negative serologic test results. In children with FSGS, the majority of whom present with nephrotic syndrome, the major differential will be between MCD and other variants of corticosteroid-resistant nephrotic syndrome. In adults with subnephrotic proteinuria, the differential includes almost all glomerular diseases without positive serologic test results. In adults with nephrotic syndrome, membranous nephropathy (MN) and MCD may present in an identical fashion, and only a renal biopsy will clarify the diagnosis. Focal sclerosing lesions due to other glomerulopathies (e.g., segmental scarring due to chronic glomerulonephritis [GN]) must be excluded. Moreover, because the defining glomerular lesion of FSGS is focal and may be confined to deeper juxtamedullary glomeruli early in the disease, it may not be sampled on renal biopsy. A large glomerular sample of more than 20 glomeruli for light microscopy increases the likelihood of identifying the diagnostic segmental lesions. Even after the diagnosis of FSGS is established, the primary (idiopathic) form must be distinguished from secondary forms by careful clinical-pathologic correlation (see Fig. 18.1). In general, many forms of postadaptive FSGS have lower levels of proteinuria than idiopathic FSGS does, a lower incidence of hypoalbuminemia, and, on biopsy, lesser degrees of foot process effacement. In patients younger than 25 years and in those with a family history of FSGS, genetic screening for mutations in podocin, nephrin, or other podocyte genes may be useful and should be performed more frequently now that these tests are becoming widely available.

PATHOLOGY

The pathologic manifestations of FSGS are heterogeneous, both qualitatively and with respect to the location of lesions within the glomerular tuft. A classification of FSGS by histologic variants has been proposed (Fig. 18.2).³⁴ This morphologic classification can be applied to both primary and secondary forms of FSGS listed in Figure 18.1. Subtypes include FSGS, classic or NOS; perihilar variant, in which more than 50% of glomeruli with segmental lesions display hyalinosis and sclerosis involving the vascular pole region; cellular variant, manifesting endocapillary hypercellularity; collapsing variant, in which at least one glomerulus has global collapse and overlying podocyte hyperplasia and hypertrophy; and tip variant, with segmental lesions involving the tubular pole. This working classification has been applied successfully to retrospective series of renal biopsies.

Morphologic Variants of Focal Segmental Glomerulosclerosis

1. FSGS, not otherwise specified (also known as classic FSGS)
2. FSGS, perihilar variant
3. FSGS, cellular variant
4. FSGS, collapsing variant (also known as collapsing glomerulopathy)
5. FSGS, tip variant

Figure 18.2 Morphologic variants of focal segmental glomerulosclerosis (FSGS).

Other more controversial histologic variants of FSGS include FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see Chapter 27). Some believe that these are distinct disease entities with unique clinical-pathologic features; others believe that they are merely subgroups of FSGS.^{35,36}

Classic Focal Segmental Glomerulosclerosis (Focal Segmental Glomerulosclerosis Not Otherwise Specified)

Classic FSGS, also called FSGS NOS, is the common generic form of FSGS. FSGS NOS requires exclusion of the other more specific subtypes described later. It is defined by accumulations of extracellular matrix that occlude glomerular capillaries, forming discrete segmental solidifications involving any portion of the tuft (Fig. 18.3).³⁴ There may be hyalinosis (plasmatic insudation of amorphous glassy material beneath the GBM), endocapillary foam cells, and wrinkling of the GBM (Fig. 18.4). Adhesions or synechiae to Bowman's capsule are common, and

Figure 18.3 Focal segmental glomerulosclerosis, not otherwise specified (FSGS, NOS). A low-power view shows four glomeruli with discrete lesions of segmental sclerosis involving a portion of the tuft. The adjacent nonsclerotic capillaries are unremarkable. In this example, there is no evidence of tubulointerstitial injury. (Jones methenamine silver; magnification $\times 100$.)

Figure 18.4 Focal segmental glomerulosclerosis, not otherwise specified (FSGS, NOS). The lesions of segmental sclerosis display increased extracellular matrix and hyalinosis. There is adhesion to Bowman's capsule without significant podocyte hypertrophy. The nonsclerotic capillaries have glomerular basement membranes of normal thickness and mild podocyte swelling. (Periodic acid-Schiff; magnification $\times 400$.)

Figure 18.5 Focal segmental glomerulosclerosis, not otherwise specified. The lesions of segmental sclerosis contain deposits of IgM corresponding to areas of increased matrix and hyalinosis. Weaker staining for IgM is also seen in the adjacent mesangium. (Immunofluorescence micrograph; magnification $\times 400$.)

Figure 18.6 Focal segmental glomerulosclerosis, not otherwise specified. An electron micrograph illustrates the lesion of segmental sclerosis with obliteration of the glomerular capillaries by increased extracellular matrix with wrinkled and retracted glomerular basement membranes. The overlying podocytes are detached with complete effacement of foot processes (double-headed arrow) and numerous electron-lucent intracellular transport vesicles (arrow). (Magnification $\times 2500$.)

overlying visceral epithelial cells often appear swollen and form a cellular “cap” over the sclerosing segment. Glomerular lobules unaffected by segmental sclerosis appear normal by light microscopy except for mild podocyte swelling. Tubular atrophy and interstitial fibrosis are commensurate with the degree of glomerular sclerosis.

On immunofluorescence (IF), there is often focal and segmental granular deposition of IgM, C3, and more variably C1 in the distribution of the segmental glomerular sclerosis (Fig. 18.5). Nonsclerotic glomeruli may have weak mesangial staining for IgM and C3.

By electron microscopy (EM), segmental sclerotic lesions exhibit increased matrix, wrinkling and retraction of the GBM, accumulation of inframembranous hyaline, and resulting narrowing or occlusion of the glomerular capillary lumina (Fig. 18.6). No immune-type electron-dense deposits are found. Overlying the segmental sclerosis, there is usually complete effacement of foot processes and podocyte hypertrophy with focal microvillous transformation (the formation of slender

Figure 18.7 Focal segmental glomerulosclerosis, perihilar variant. A discrete lesion of segmental sclerosis and hyalinosis is located at the glomerular vascular pole (i.e., perihilar). The glomerulus is hypertrophied. The patient had secondary FSGS in the setting of solitary kidney due to contralateral renal agenesis. (Periodic acid–Schiff; magnification $\times 250$.)

cellular projections resembling villi along the surface of the podocytes). The adjacent nonsclerotic glomerular capillaries show only foot process effacement.

Perihilar Variant of Focal Segmental Glomerulosclerosis

The perihilar variant is defined as perihilar hyalinosis and sclerosis that involve more than 50% of glomeruli with segmental lesions.³⁴ This category requires that the cellular, tip, and collapsing variants be excluded. Podocyte hyperplasia is uncommon. IF reveals segmental deposits of IgM and C3 in areas of sclerosis and hyalinosis. There is variable foot process effacement. Although the perihilar variant may occur in primary FSGS, it is particularly common in secondary forms of FSGS mediated by adaptive structural-functional responses, in which it is typically accompanied by glomerular hypertrophy (Fig. 18.7). In this setting, the greater filtration pressures at the proximal end of the glomerular capillary bed may favor the development of lesions at the vascular pole.⁷

Cellular Variant of Focal Segmental Glomerulosclerosis

The cellular variant is characterized by focal and segmental endocapillary hypercellularity that may mimic a form of focal proliferative glomerulonephritis.³⁷ Glomerular capillaries are segmentally occluded by endocapillary hypercellularity, including foam cells, infiltrating leukocytes, karyorrhectic debris, and hyaline (Fig. 18.8). There is often hyperplasia of the visceral epithelial cells, which may appear swollen and crowded, sometimes forming pseudocrescents. This variant requires that tip lesions and collapsing lesions be excluded. IF microscopy again shows focal and segmental glomerular positivity for IgM and C3. EM reveals severe foot process effacement.

Collapsing Variant of Focal Segmental Glomerulosclerosis

The collapsing variant is defined by at least one glomerulus with segmental or global collapse and overlying hypertrophy and

Figure 18.8 Focal segmental glomerulosclerosis (FSGS), cellular variant. The glomerular capillary lumina are segmentally occluded by endocapillary cells, including foam cells, infiltrating mononuclear leukocytes, and pyknotic debris. The findings mimic a proliferative glomerulonephritis because of the hypercellularity and absence of extracellular matrix material. There are hypertrophy and hyperplasia of the overlying podocytes, some of which contain protein resorption droplets. (Jones methenamine silver; magnification $\times 400$.)

Figure 18.9 Focal segmental glomerulosclerosis (FSGS), collapsing variant. There is global implosive collapse of the glomerular tuft with obliteration of capillary lumina. The overlying podocytes appear hypertrophied and hyperplastic with enlarged nuclei and nucleoli. There are no adhesions to Bowman's capsule. (Jones methenamine silver; magnification $\times 400$.)

hyperplasia of visceral epithelial cells (Fig. 18.9). In these areas, there is occlusion of glomerular capillary lumina by implosive wrinkling and collapse of the GBMs.^{32,33} This lesion is more often global than segmental. Overlying podocytes display striking hypertrophy and hyperplasia and express proliferation markers. Podocytes often contain prominent intracytoplasmic protein resorption droplets and may fill Bowman's space, forming pseudocrescents (Figs. 18.10 and 18.11). Although podocyte hyperplasia is found in both the collapsing and cellular variants of FSGS, collapsing glomerulopathy is distinguished by the absence of endocapillary hypercellularity. In collapsing FSGS, there is prominent tubulointerstitial disease, including tubular atrophy, interstitial fibrosis, interstitial edema, and inflammation. A distinctive feature is the presence of dilated tubules forming microcysts that contain loose proteinaceous casts.

The collapsing lesions often have positivity for IgM and C3 by IF. On EM, there is typically severe foot process effacement affecting both collapsed and noncollapsed glomeruli (Fig. 18.12). Collapsing glomerulopathy may occur as a primary form of

Figure 18.10 Focal segmental glomerulosclerosis (FSGS), collapsing variant. In this example, the exuberant proliferation of visceral epithelial cells forms a pseudocrescent that obliterates the urinary space. The pseudocrescent lacks the spindle cell morphology, ruptures of Bowman's capsule, or pericellular matrix typically seen in true inflammatory crescents of parietal epithelial origin. (Jones methenamine silver; magnification $\times 400$.)

Figure 18.11 Focal segmental glomerulosclerosis (FSGS), collapsing variant. The crescent-like proliferation of glomerular epithelial cells contains numerous intracytoplasmic vacuoles and trichrome-red protein resorption droplets (arrows). (Masson trichrome; magnification $\times 400$.)

Figure 18.12 Focal segmental glomerulosclerosis, collapsing variant. On electron microscopy, there is tight collapse of the glomerular capillaries with corrugated glomerular basement membrane. The overlying podocytes appear detached and hypertrophied with complete loss of foot processes. (Magnification $\times 2500$.)

Figure 18.13 Focal segmental glomerulosclerosis (FSGS), collapsing variant, due to pamidronate toxicity. The glomerular tuft is retracted, without appreciable increase in matrix material. The overlying podocytes are enlarged and hyperplastic (arrows), with numerous intracytoplasmic vacuoles and protein resorption droplets. (Jones methenamine silver; magnification $\times 400$.)

Figure 18.15 Focal segmental glomerulosclerosis (FSGS), tip lesion variant. A sclerosing tip lesion forms an adhesion to the tubular pole (arrow). (Periodic acid-Schiff; magnification $\times 250$.)

Figure 18.14 Focal segmental glomerulosclerosis (FSGS), tip lesion variant. A cellular tip lesion displays engorgement of glomerular capillaries by foam cells and adhesion of the involved segment to the origin of the proximal tubule (tubular pole). (Periodic acid-Schiff; magnification $\times 250$.)

FSGS.^{32,33} This pattern is also commonly observed in secondary FSGS due to HIV infection, parvovirus B19 infection, interferon therapy, and pamidronate toxicity (Fig. 18.13). The presence of endothelial tubuloreticular inclusions is helpful to identify collapsing glomerulopathy secondary to HIV-associated nephropathy or interferon therapy.

Tip Variant of Focal Segmental Glomerulosclerosis

This variant is defined by the presence of at least one segmental lesion involving the tip domain (i.e., the outer 25% of the tuft next to the origin of the proximal tubule).³¹ There is either adhesion between the tuft and Bowman's capsule or confluence of swollen podocytes with parietal or tubular epithelial cells at the tubular lumen or neck. In some cases, the affected segment appears to herniate into the tubular lumen. The segmental lesions may be cellular or sclerosing in type (Figs. 18.14 and

18.15). Although initially peripheral, these lesions may evolve more centrally. Whereas the FSGS glomerular tip lesion may occur alone or with segmental lesions that are peripheral or indeterminate in location, the presence of perihilar sclerosis or collapsing sclerosis rules out the tip variant. In one study of FSGS tip lesions, biopsy specimens had glomerular tip lesions alone in 26% and glomerular tip lesions plus other peripheral FSGS lesions in the other 74%.³¹ IF and EM findings are similar to those of other biopsies with FSGS. Most cases are idiopathic. Higher shear stress and tuft prolapse at the tubular pole are likely to play a role in the morphogenesis of this lesion.

Other Variants of Focal Segmental Glomerulosclerosis

Two histologic variants often included within the FSGS spectrum are FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see also Chapter 27).^{5,35,36} FSGS with diffuse mesangial hypercellularity has lesions of FSGS on a background of generalized mesangial hypercellularity. By IF, there is diffuse mesangial positivity for IgM, with more variable mesangial staining for C3; by EM, there is extensive foot process effacement without glomerular electron-dense deposits. This variant occurs almost exclusively in young children.

C1q nephropathy is an idiopathic glomerulopathy defined by dominant or codominant IF staining for C1q, mesangial electron-dense deposits, and light microscopic findings resembling FSGS or MCD with variable mesangial hypercellularity. In one study, 17 patients had a light microscopic appearance of FSGS (including six collapsing and two cellular) and three of MCD.³⁵ In addition to C1q staining, biopsy specimens may show deposition of other immunoglobulins (particularly IgG) and complement components (C3), making exclusion of other clinical disease entities important (e.g., lupus nephritis, membranoproliferative glomerulonephritis [MPGN]). In C1q nephropathy, electron-dense deposits are typically located predominantly in the paramesangial region subjacent to the GBM reflection. There is variable foot process effacement. The largest series of C1q nephropathy supports that many cases represent a subgroup of primary FSGS or MCD, whereas others are an idiopathic immune complex-mediated glomerulonephritis.³⁶

Figure 18.16 Human immunodeficiency virus–associated nephropathy. A globally collapsed glomerulus shows marked podocyte hypertrophy and hyperplasia. (Jones methenamine silver; magnification $\times 400$.)

Figure 18.17 Human immunodeficiency virus–associated nephropathy. At low power, the renal parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space. (Periodic acid–Schiff; magnification $\times 80$.)

Distinguishing Pathologic Features of Secondary Focal Segmental Glomerulosclerosis

Although the pathology of some secondary forms of FSGS resembles closely that of primary FSGS, there are several noteworthy differences. Whereas the light microscopic findings in HIV-associated nephropathy are similar to those of idiopathic collapsing FSGS (Fig. 18.16), tubular microcysts are particularly common (Fig. 18.17).³⁸ By EM, a major difference is the abundance of tubuloreticular inclusions in the glomerular endothelial cells of HIV-associated nephropathy. These “interferon footprints” consist of 24-nm interanastomosing tubular structures located within dilated cisternae of endoplasmic reticulum (Fig. 18.18). Tubuloreticular inclusions have become less frequent in patients treated with highly active antiretroviral therapy.³⁸

In secondary postadaptive forms of FSGS, renal biopsy typically shows glomerulomegaly and predominantly perihilar lesions of segmental sclerosis and hyalinosis. In secondary FSGS resulting from loss of renal mass (such as due to reflux nephropathy or hypertensive arterionephrosclerosis), FSGS is usually seen on a background of extensive global glomerulosclerosis, tubular atrophy, interstitial fibrosis, and arteriosclerosis. In secondary FSGS related to sickle cell disease, there is glomerular

Figure 18.18 Human immunodeficiency virus–associated nephropathy. The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion (“interferon footprint”; arrow) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum. (Electron micrograph; magnification $\times 15,000$.)

Figure 18.19 Secondary focal segmental glomerulosclerosis (FSGS) due to obesity. By light microscopy, this patient with morbid obesity had glomerular hypertrophy and predominantly perihilar lesions of segmental sclerosis and hyalinosis. The foot processes show mild effacement involving approximately 20% of the glomerular capillary surface area despite the presence of nephrotic-range proteinuria (electron micrograph). This mild degree of foot process effacement is less than that usually seen in primary FSGS. (Magnification $\times 2500$.)

hypertrophy and sclerosis in association with capillary congestion by sickled erythrocytes and double contours of the GBM resembling those seen in chronic thrombotic microangiopathy. Importantly, in secondary postadaptive forms of FSGS, the degree of foot process effacement tends to be relatively mild, affecting less than 50% of the total glomerular capillary surface area, with correspondingly shorter foot process width (Fig. 18.19). In one study, a cutoff of more than 1500 nm for mean foot process width was able to distinguish primary from secondary (postadaptive) FSGS with high sensitivity and specificity.³⁹

NATURAL HISTORY AND PROGNOSIS

The natural history of FSGS is varied.^{1–3} Without therapy or response to therapy, the majority of patients with primary FSGS

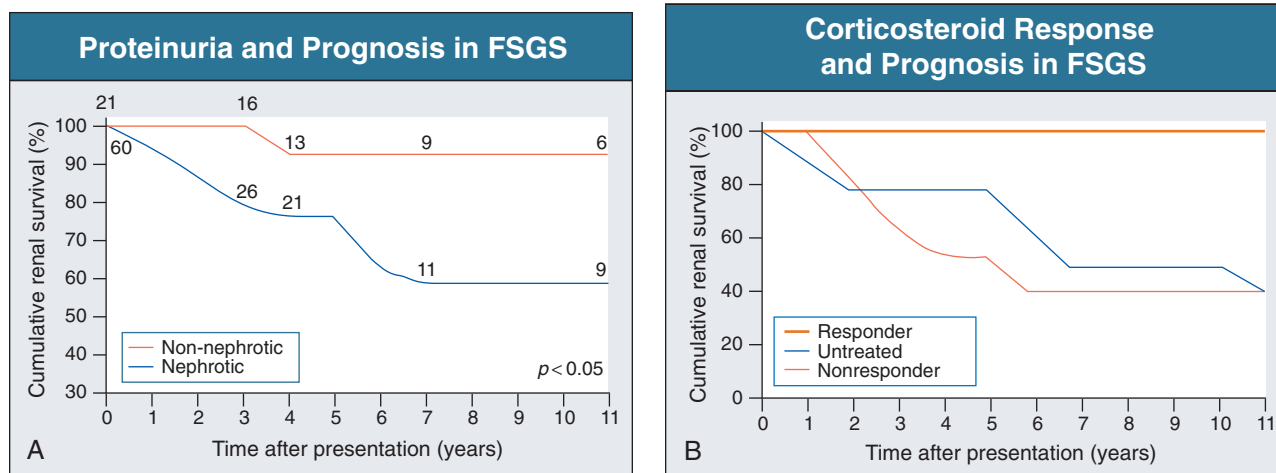

Figure 18.20 Prognosis in primary focal segmental glomerulosclerosis (FSGS). **A**, The risk for development of renal failure is related to the extent of proteinuria. Those with nephrotic-range proteinuria are much more likely to develop renal failure than are those with low-grade proteinuria. The figures indicate the number of at-risk patients at different time points. **B**, Corticosteroid-responsive patients are significantly less likely to develop renal failure than are nonresponders and untreated patients. (Modified from reference 67.)

Risk Factors for Progressive Renal Disease in Focal Segmental Glomerulosclerosis

Clinical features at time of biopsy
Nephrotic-range proteinuria or massive proteinuria
Elevated serum creatinine
Black race
Histopathologic features at time of biopsy
Collapsing variant
Tubulointerstitial fibrosis
Clinical features during the course of FSGS
Failure to achieve partial or complete remission

Figure 18.21 Risk factors for progressive renal disease in focal segmental glomerulosclerosis (FSGS).

will experience a progressive increase in proteinuria and progression to renal failure. Only 5% to 25% of patients undergo a spontaneous remission of proteinuria.⁴⁰ Both unresponsive children and adults have a similar course; most develop ESRD 5 to 20 years from presentation, with approximately 50% of such patients reaching ESRD by 10 years (Fig. 18.20).

Certain epidemiologic, clinical, and histologic findings at the time of diagnosis help predict the long-term course of FSGS patients (Fig. 18.21).¹⁻⁵ African Americans, even when controlled for degree of proteinuria, hypertension, and other features, experience a more rapid progression to renal failure. At biopsy, reduced GFR, greater degrees of proteinuria, and greater degrees of interstitial fibrosis predict a more progressive course.¹ The degree of glomerulosclerosis has been much less consistent as a prognostic finding.¹⁻⁵ Patients who experience a remission of proteinuria and the nephrotic syndrome have a far better renal survival than those who do not.^{1,3,41,42} Even patients with a partial remission of nephrotic syndrome have a lower rate of long-term renal failure.⁴³

There is a consensus that outcomes are best for tip variant and worst for collapsing variant of primary FSGS.^{37,44,45} In a comparative series, the percentage of complete and partial remission was greatest for tip lesion (76%), lowest for collapsing

variant (13%), and intermediate for cellular (44%), compared with 39% for FSGS NOS.³⁷ There was a strong inverse correlation between remission rates and progression to ESRD among these subgroups. Accordingly, the percentage ESRD was greatest for collapsing variant (65%), lowest for tip lesion (6%), and intermediate for cellular variant (28%), compared with 35% for FSGS NOS.³⁷

TREATMENT

There is still considerable debate about the appropriate treatment of patients with FSGS^{1-3,42} (Fig. 18.22). In part, this relates to confusion between primary and secondary forms of the disease, including unrecognized genetic variants. Even after biopsy, it is not always clear whether an obese person with glomerulomegaly and many segmentally sclerotic lesions has secondary or primary disease.¹⁸ Moreover, the course of the disease is variable, and only recently have clear prognostic features been defined. Finally, although the disease is common in adults, there are many therapeutic options with few randomized, controlled trials on which to base judgment.

In early studies of FSGS, only 10% to 30% of those treated with corticosteroids for relatively short periods or other immunosuppressive agents experienced a remission of proteinuria, and the relapse rate was high.^{1,42} Thus, many nephrologists considered FSGS to be a resistant disease and did not advocate immunosuppressive treatment. A classic study about 20 years ago documented that in Toronto, almost all children with FSGS were treated with immunosuppressives and that 44% experienced a remission.⁴¹ Although the response rate for treated adults was similar (39%), most of the adults never received any immunosuppressive therapy.⁴¹

Use of Corticosteroids

In recent trials using longer (>6 months) courses of corticosteroids, the results have been much more promising. Therapy is usually with prednisone or prednisolone, 1 mg/kg/day or 1.5 to 2 mg/kg every other day for an initial period of 4 to 8 weeks, with subsequent tapering of the dose.^{1,3,42} Initial response rates

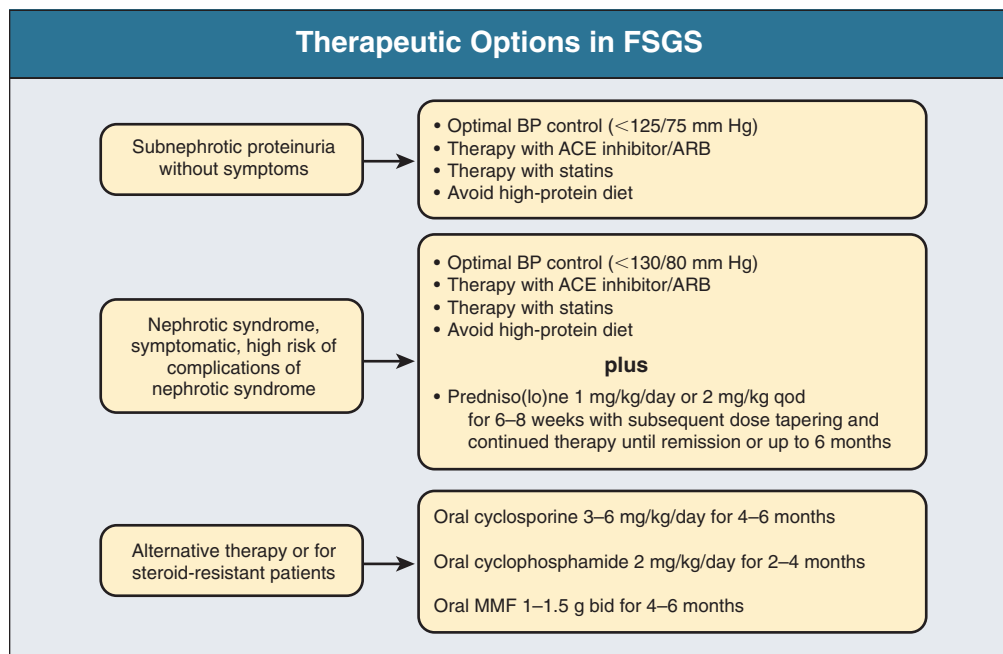

Figure 18.22 Therapeutic options in focal segmental glomerulosclerosis. For secondary FSGS treatment directed at the underlying cause (e.g., human immunodeficiency virus–associated nephropathy: treatment with highly active antiretroviral therapy; pamidronate nephrotoxicity: discontinue the medication; obesity-related glomerulopathy: weight loss). ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; MMF, mycophenolate mofetil.

range from 40% to 80%. In children with biopsy-documented FSGS, 20% to 25% will have a complete remission with a short course of corticosteroids, but 50% will remit with more intensive therapy. In adults, although there are no large or randomized, controlled trials, more prolonged use of corticosteroids has led to much higher remission rates of nephrotic syndrome than in earlier studies.^{1,3,42,46,47} The median duration of corticosteroid treatment for complete remission to be achieved is 3 to 4 months; most patients respond by 6 months. Most clinicians would treat all nephrotic FSGS patients and those at risk of progressive disease with a prolonged course (6 to 9 months) of daily or every-other-day corticosteroid therapy or other immunosuppressive medication in the hope of inducing a remission of nephrotic syndrome and preventing eventual ESRD. The corticosteroid dose should be tapered after 6 to 8 weeks to avoid cushingoid side effects.

Other Immunosuppressive Agents

For many years, either chlorambucil or cyclophosphamide combined with corticosteroids was the treatment of choice for children and for adults with corticosteroid-resistant FSGS.^{1,48} One uncontrolled trial in children using combined intravenous pulse corticosteroids and long-term immunosuppression with corticosteroids and cytotoxics found a 60% complete remission rate and a 16% partial remission rate of the nephrotic syndrome and a low rate of progression to renal failure.⁴⁹ In adults with FSGS treated with either oral cyclophosphamide or chlorambucil, pooled data show a high response rate for patients with corticosteroid dependence or intolerance but a remission rate of only less than 20% for those who are corticosteroid resistant.⁴²

A number of studies have used low-dose cyclosporine (3 to 6 mg/kg/day for 2 to 6 months) to treat corticosteroid-resistant FSGS (Fig. 18.23).^{50,51} Complete plus partial remission rates of

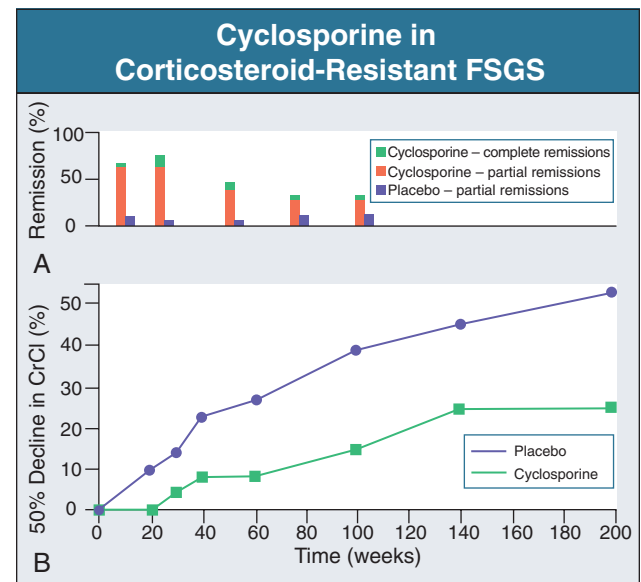

Figure 18.23 Cyclosporine in corticosteroid-resistant focal segmental glomerulosclerosis (FSGS). A randomized, controlled trial of 6 months of treatment with prednisolone and either cyclosporine or placebo. **A**, Cyclosporine induces a partial or complete remission significantly more often than placebo does. **B**, Cyclosporine treatment results in a lower rate of decline in renal function than with placebo even after 4 years. CrCl, creatinine clearance. (Modified from reference 51.)

60% to 70% have been achieved versus only 17% to 33% in the placebo groups. Adult North American FSGS patients randomized to either cyclosporine with low-dose corticosteroids or the same low dose of corticosteroids alone for a 6-month period exhibited a much higher remission rate (12% complete and >70% complete or partial) in the group treated with

cyclosporine.⁵¹ Despite relapses after the cyclosporine was discontinued, at the end of long-term follow-up, there were still significantly more remitters in the treated group. Moreover, despite initial worries about cyclosporine nephrotoxicity, the percentage of patients with reduction of GFR during 4 years was significantly less in the treated group. It is unclear whether the low dose and short course of cyclosporine (6 months) contributed to this beneficial result. Nevertheless, because there is a high relapse rate when the drug is discontinued, many clinicians use a 1-year course with slow taper in patients who have a favorable reduction of proteinuria with cyclosporine.^{1,42}

Although data are more limited with tacrolimus and there are no large controlled trials, the results have been similar.^{52,53} Because the major side effects of nephrotoxicity, hypertension, and hyperkalemia are the same for both drugs, choice may depend on cosmetic and other less severe adverse side effects (e.g., gum swelling, tremor, hirsutism). Tacrolimus has been effective in some patients who are resistant to or intolerant of cyclosporine.

A multicenter German collaborative study compared the efficacy and safety of corticosteroids plus cyclosporine with corticosteroids plus chlorambucil in corticosteroid-resistant adults with FSGS and nephrotic syndrome.⁵⁴ Total and partial remission rates were similar (about 20% full and 40% to 50% partial remission), and the addition of chlorambucil to the regimen did not improve outcome. Whether cyclosporine is equivalent or superior to corticosteroids as first-line therapy for FSGS has never been documented. However, some clinicians use cyclosporine as first-line therapy in patients at high risk of corticosteroid complications, such as those with concurrent diabetes or morbid obesity.

Mycophenolate mofetil (MMF) has been used in several uncontrolled series of FSGS patients.^{55,56} In some, including those resistant to other therapies, there have been remissions of nephrotic syndrome and major reductions in proteinuria. A multicenter trial comparing cyclosporine and a regimen of oral MMF plus dexamethasone in corticosteroid-resistant FSGS is ongoing in the United States.

The use of sirolimus has been controversial since the drug was reported to induce proteinuria and FSGS lesions in kidney transplant patients. Sirolimus has been used in several small series of patients with glomerular disease including FSGS patients.^{57,58} In one series, it was associated with worsening of renal function, episodes of acute renal failure, and no remissions of the nephrotic syndrome.⁵⁷ In another series, which included 21 corticosteroid-resistant FSGS patients, 19% experienced a complete remission, 38% a partial remission, and, hence, more than 50% a beneficial result.⁵⁸ Patients who responded to treatment had a shorter duration of FSGS than did resistant patients. Given the controversy about efficacy and toxicity, sirolimus should be considered experimental therapy until more data are available.

Rituximab has been used in small numbers of FSGS patients with anecdotal success. Most regimens have included other concomitant immunosuppressive therapies. A study found only three of eight corticosteroid-resistant adult patients with FSGS to benefit from such therapy.⁵⁹

Plasma exchange, which is successful in treating some patients with recurrent FSGS in the renal allograft (see Chapter 104), has not proved useful in patients with disease in their native kidneys.¹³ A study of low-density lipoprotein apheresis and prednisone in corticosteroid- and cyclosporine-resistant children with primary FSGS achieved a remission in 7 of 11 patients.⁶⁰ Unfortunately,

the role of the individual components of treatment and the mechanisms of action are difficult to define in such uncontrolled trials.

Other Therapeutic Interventions

The role, if any, of corticosteroids and other immunosuppressives in the treatment of patients with subnephrotic levels of proteinuria and little damage on renal biopsy is unclear. This group is less likely to have progressive disease and to benefit from immunosuppression. Most would treat all FSGS patients without contraindications with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) as well as statins, similar to other progressive glomerular diseases (see Chapter 76). Clearly, optimal blood pressure control itself is also critical to slow or to prevent the progression of the disease (see also Chapter 76).

Galactose, a monosaccharide sugar, has been shown to have a high affinity for the cardiotrophin-like cytokine 1 permeability factor.⁶¹ In at least one patient with FSGS resistant to multiple immunosuppressive regimens, long-term galactose therapy normalized the permeability factor and dramatically reduced proteinuria.⁶² Recent data confirm that glomerular permeability can be improved in most FSGS patients with galactose, although the effects on proteinuria remain to be proved.

Another area of active research is the use of agents to prevent renal fibrosis in patients with FSGS. Pirfenidone, an oral TGF- β inhibitor, was used in 21 patients with FSGS and a declining GFR.⁶³ The drug slowed the loss of kidney function over time without altering either blood pressure or proteinuria. A study using an antibody to TGF- β is ongoing in FSGS patients.

For patients with secondary forms of FSGS, attempts to treat the primary cause of the FSGS should be the initial step in management. Patients with FSGS secondary to obesity and heroin nephropathy have had remissions of proteinuria after weight reduction or cessation of heroin use, respectively. In patients with HIV-associated nephropathy, therapy with highly active antiretroviral drugs and blockers of the renin-angiotensin system (RAS) has proved useful (see Chapter 56). The role of immunosuppressives has not yet been documented in controlled, randomized trials in any form of secondary FSGS. In all forms of secondary FSGS, supportive therapy as outlined in Chapter 76 is essential to prevent progressive renal disease in this population. In those patients with either primary idiopathic or secondary forms of FSGS who remain nephrotic, control of fluid retention and edema can be managed with salt restriction and diuretics (see Chapter 15).

TRANSPLANTATION

Idiopathic FSGS may recur in the transplanted kidney, in which it presents with severe proteinuria and nephrotic syndrome (see Chapter 104).⁶⁴ Children with FSGS and patients who manifest with more severe proteinuria and a more rapid course to renal failure in their native kidneys are at greater risk of recurrence in the allograft. Those who have lost a prior allograft because of recurrent FSGS are at highest risk of recurrence. Recurrence in the allograft may be seen immediately after transplantation, supporting the existence of a circulating factor, or years later. Interestingly, the histologic variant of recurrent FSGS was the same as that documented in the native kidney in 81% of cases, validating the fidelity of the histologic subclassification.¹⁰ Plasma exchange has been used successfully to induce

remissions of the proteinuria associated with recurrence, but the results are more favorable in children than in adults. Rituximab has been used in some patients for recurrent FSGS with varied outcomes.

Analysis of the outcomes of renal transplantation in children with FSGS shows a profound effect of race.⁶⁵ Among African American children with FSGS, allograft survival was not different from that of non-FSGS patients. Among non-African American children with FSGS, the risk of allograft failure was 1.3 times higher than for other causes of ESRD. Nevertheless, for non-African American children, a transplant from a living related donor gave a better allograft survival than that from a cadaveric donor. An analysis of all FSGS transplants in the United States Renal Data System (USRDS) database showed no risk of graft loss for zero-mismatched transplants in FSGS patients.⁶⁶ However, this analysis may have included patients with secondary forms of FSGS that would be unlikely to recur, thereby underestimating the overall risk of recurrence. Whereas most patients with genetic forms of FSGS have not experienced a recurrence in the allograft, this is not universally true, especially in those with compound heterozygous mutations.

Inherited Causes of Nephrotic Syndrome

Jason Eckel, Michelle Winn

DEFINITION

Inherited nephrotic syndromes are rare diseases that present with nephrotic syndrome and varying degrees of renal impairment but at times may also present with subnephrotic proteinuria. They can be manifested *in utero* or shortly after birth, as in congenital nephrotic syndromes, or later in life with proteinuria and pathologic findings consistent with focal segmental glomerulosclerosis (FSGS). FSGS as the cause of nephrotic syndrome in adults is increasing according to biopsy studies in some but not all countries (see also Chapter 18). Some believe that up to 18% of cases of FSGS are due to hereditary disorders.¹ Autosomal dominant and recessive renal diseases result from defects in podocytes, the slit diaphragm, and the glomerular basement membrane (GBM). These primary renal disorders by definition do not recur after kidney transplantation. In children, syndromic conditions may be seen in which mutations in transcription factors involved in the development of multiple organ systems can also affect renal morphogenesis and result in glomerulopathy. Further insight into these hereditary diseases has been elucidated through animal models, in which mutations in corresponding proteins often result in FSGS and proteinuria. Understanding of these mechanisms not only provides better insight into abnormalities involved in idiopathic proteinuric kidney diseases but also allows the possible development of molecular drug targets that may improve the course of the renal disease and delay progression.²⁻⁴

AUTOSOMAL RECESSIVE DISEASES

Congenital Nephrotic Syndrome of the Finnish Type

In 1956, Hallman described a disorder of massive proteinuria *in utero* in the Finnish population. Congenital nephrotic syndrome of the Finnish type (CNF) or nephrotic syndrome type 1 (NPHS1) is an autosomal recessive disease. It has an incidence of 1 in 8200 births in Finland and has been reported less frequently in other ethnicities. The placenta is larger than the child at birth, and the baby is usually born prematurely. Affected children will have as much as 30 g of proteinuria per day, massive edema, hypoalbuminemia, and hyperlipidemia. By light microscopy, kidneys typically have cystic dilation of the proximal tubules and diffuse mesangial sclerosis (Fig. 19.1). Effacement of podocyte foot processes and loss of the glomerular slit diaphragm are seen with electron microscopy.²

Genome-wide linkage analysis localized the gene (*NPHS1*) to chromosome 19q13.1. The product of the *NPHS1* gene is specifically expressed in podocytes, localized to the slit diaphragm

between podocyte foot processes, and is now named nephrin.³ Nephrin is a transmembrane protein belonging to the immunoglobulin superfamily. The nephrin molecule has an intracellular, transmembrane, and extracellular domain. The extracellular domain forms the zipper-like structure of the slit diaphragm; the short intracellular domain interacts with the podocyte proteins podocin and CD2-associated protein (CD2AP). The most common mutations in nephrin are termed Fin-major and Fin-minor and account for 95% of the disease, but more than 50 other mutations in nephrin have also been reported.⁴ The importance of nephrin in the function of the glomerular barrier has been demonstrated in mice; *NPHS1* knockout mice have massive proteinuria, have absence of a slit diaphragm, and die within 24 hours of birth.⁵

CNF does not respond to cytotoxic therapy or corticosteroids. Angiotensin-converting enzyme (ACE) inhibitors and nonsteroidal anti-inflammatory drugs (NSAIDs) have no effect on reducing proteinuria in those with the Fin-major mutation, but there are some reports of efficacy of these agents in those with other mutations in nephrin. The ultimate goal of treatment of CNF is renal transplantation as mortality without this approach is nearly 100%. Because of overwhelming urinary loss of protein, affected infants without the Fin-major mutation may require medical nephrectomy with ACE inhibitors and NSAIDs followed by renal replacement therapy (RRT) before transplantation. There is a risk of recurrence of nephrotic syndrome in patients after transplantation, perhaps in as many as 20% to 25%. This is thought to be due to the introduction of a normal structural and functional nephrin in the transplanted kidney that sometimes leads to the production of anti-nephrin alloantibodies, which may be pathogenic.^{2,4}

Corticosteroid-Resistant Nephrotic Syndrome

In children with nephrotic syndrome of unknown etiology, 90% of cases respond to corticosteroids. Of those who do not respond to corticosteroids, many have nephrotic syndrome type 2 (NPHS2), also known as corticosteroid-resistant nephrotic syndrome, an autosomal recessive disease seen mostly in children younger than 5 years.⁶ Affected children have nephrotic-range proteinuria and rapid progression to end-stage renal disease (ESRD). As the disease name implies, patients do not respond to corticosteroids and suffer the extrarenal complications of massive proteinuria. By light microscopy, the renal lesions that have been seen vary along the spectrum of minimal change disease (MCD) to FSGS.⁴ The gene *NPHS2* (nephrotic syndrome, type 2) was mapped to chromosome 1q25-q31 and determined to be the cause of corticosteroid-resistant nephrotic

Figure 19.1 Congenital nephrotic syndrome, Finnish type. **A**, Diffuse mesangial thickening and partially collapsed glomeruli. (Periodic acid–Schiff; magnification $\times 260$.) **B**, Microcystic dilation of the tubules. (Hematoxylin–eosin; magnification $\times 150$.) (Modified from reference 23.)

syndrome.⁷ Similar to the *NPHS1* gene product nephrin, the product of *NPHS2* is specifically expressed in podocytes in the kidney and is named podocin. Podocin is hairpin shaped and found along the podocyte membrane with both ends directed intracellularly (Fig. 19.2).² Podocin localizes to the foot processes and seems to be involved in podocyte structure as well as in intracellular signaling, with the recruitment of nephrin and CD2AP to microdomains along the slit diaphragm.⁴

The description of corticosteroid-resistant nephrotic syndrome attributed to the *NPHS2* mutation represents a condition seen in children between 3 months and 5 years of age. It appears that when the disease is manifested depends on the specific podocin mutation. The presence of at least one podocin mutation that codes for a stop codon or in patients homozygous for the R138Q mutation results in renal disease at around the age of 2 years. Two missense podocin mutations cause disease just before the age of 5 years. Furthermore, studies demonstrate podocin mutations in adult-onset forms of FSGS. This is seen around the end of the second decade. These patients must have two podocin mutations, one of which must be the podocin R229Q mutation.⁸

Isolated Diffuse Mesangial Sclerosis

Diffuse mesangial sclerosis is a pathologic finding in some cases of early-onset nephrotic syndrome. It is described as either syndromic, when it is associated with a particular clinical syndrome, or isolated, when the only manifestation is renal disease. The isolated disease presents as nephrotic syndrome in the first month of life with rapid progression to ESRD. By light microscopy, findings include podocyte hypertrophy, mesangial

Figure 19.2 Podocyte foot process structure and proteins involved in hereditary nephrotic syndromes. The podocyte contains F-actin, myosin (M), and actin-binding proteins synaptopodin (S) and α -actinin-4 (α ACTN4). α ACTN4 is mutated in FSGS type 1. The slit diaphragm contains proteins that include nephrin, podocin, and CD2AP. Nephrin is mutated in congenital nephrotic syndrome of the Finnish type, and podocin in corticosteroid-resistant nephrotic syndrome. Zona occludens 1 (ZO-1) is a cell-to-cell junction protein. PLC ϵ 1 is an enzyme identified as a cause of diffuse mesangial sclerosis. Angiotensin receptor 1 is an example of a G protein–coupled receptor (GPCR) and can activate TRPC6. A TRPC6 mutation in FSGS type 2 results in increased calcium (Ca^{2+}) transients. INF2 (not shown) is mutated in FSGS type 5 and causes mislocalization of the INF2 protein. Talin, paxillin, and vinculin (TPV) are connected to laminin II through $\alpha_3\beta_1$ integrin dimers and are involved in anchoring of the podocyte to the glomerular basement membrane (GBM). The LAMB2 mutation is responsible for Pierson's syndrome and results in diffuse mesangial sclerosis. LCAT deficiency demonstrates lipid deposits in the GBM. Laminated apolipoprotein deposits (ApoE) are found in the capillaries in lipoprotein glomerulopathy. LMX1B and WT1 (not shown) are transcription factors mutated in syndromic proteinuric renal diseases. Catenins (CAT), p130Cas (CAS), and focal adhesion kinase (FAK) are structural proteins. (Modified from reference 24.)

matrix expansion, thickened basement membranes, and decreased size of glomerular capillary lumina. In addition, some cases have shown response to cyclosporine.⁹

Diffuse mesangial sclerosis is inherited in an autosomal recessive pattern (Fig. 19.3). In 12 children with isolated diffuse mesangial sclerosis, the causative gene was mapped to chromosome 10q23. The gene *PLCE1* encodes phospholipase C epsilon 1 (PLC ϵ 1). PLC ϵ 1 is a phospholipase involved in the generation of diacylglycerol and inositol 1,4,5-trisphosphate, which are intracellular second messengers (see Fig. 19.2). Evidence of the role of PLC ϵ 1 in glomerular function was demonstrated in a *plc 1* knockout model in zebrafish. These animals had edema and pathologic characteristics of nephrotic syndrome during development. The mechanism of disease from the *PLCE1* mutation is not clear, but there is evidence that it interacts with a GTPase-activating protein involved in podocyte development and interaction with nephrin. *PLCE1* is not the only gene responsible for isolated diffuse mesangial sclerosis; more genetic causes are

Autosomal Recessive Nephrotic Syndromes				
Disease	Gene	Protein	Clinical Presentation	Mechanism of Disease
Congenital nephrotic syndrome of the Finnish type	<i>NPHS1</i>	Nephrin	Proteinuria <i>in utero</i> (sometimes >30 grams), large placenta, resistant to conventional therapy, transplant is the only treatment	Mutation in nephrin leads to loss or malfunction of the slit diaphragm
Steroid resistant nephrotic syndrome	<i>NPHS2</i>	Podocin	Various clinical manifestations and age of onset of proteinuria; resistant to steroids, generally progresses to FSGS	Mutation in podocin leads to loss or malfunction of the slit diaphragm
Isolated diffuse mesangial sclerosis	<i>PLCE1</i>	PLC ϵ 1	Nephrotic syndrome in the first year of life; rapid progression to ESRD	Unclear, but PLC ϵ 1 mutation results in abnormal podocyte differentiation potentially through nephrin; other mutations exist not attributed to <i>PLCE1</i>

Figure 19.3 Autosomal recessive nephrotic syndromes. ESRD, end-stage renal disease; FSGS, focal segmental glomerulosclerosis.

Autosomal Dominant Nephrotic Syndromes				
Disease	Gene	Protein	Clinical Presentation	Mechanism of Disease
FSGS type 1	<i>ACTN4</i>	α -actinin-4	Slow progression to ESRD; generally presents in adulthood with proteinuria	Mutation in α -actinin-4 results in abnormal assembly/disassembly of actin and podocyte structural abnormalities
FSGS type 2	<i>TRPC6</i>	TRPC6	Proteinuria seen in late adolescence to adulthood; 60% progress to ESRD by 10 years	Mutation in TRPC6 leads to increased calcium transients, which may result in disruption of podocyte structure or function
FSGS type 5	<i>INF2</i>	INF2	Moderate proteinuria seen in late adolescence to adulthood; occasional microscopic hematuria and hypertension	Mutation in INF2 causes mis-localization of the protein

Figure 19.4 Autosomal dominant nephrotic syndromes. ESRD, end-stage renal disease; FSGS, focal segmental glomerulosclerosis.

under investigation, and further mechanisms as to the cause of this distinct clinicopathologic entity are yet to be defined.⁹

AUTOSOMAL DOMINANT DISEASES

Autosomal Dominant Familial Focal Segmental Glomerulosclerosis

In contrast to inherited nephrotic syndromes that present in childhood, there are familial proteinuric kidney diseases that are manifested in adolescence through adulthood. Most of these are inherited in an autosomal dominant fashion (Fig. 19.4). Typical pathology reveals the glomerular changes of FSGS, and there is variability in the rate of progression of renal impairment. Genetic mutations have been identified, and mechanisms of FSGS in sporadic forms can be elucidated from our increasing understanding of these familial cases.¹⁰

FSGS type 1 is an autosomal dominant form of FSGS caused by mutations in *ACTN4*, which has been mapped to chromosome 19q13.² The product of this gene is α -actinin 4, which is

expressed in podocytes and cross-links with F-actin filaments in the foot processes (see Fig. 19.2). The mutation in *ACTN4* is believed to be a gain-of-function mutation, leading to increased cross-linking of F-actin with α -actinin 4, resulting in dysregulation of actin assembly and disassembly in the podocyte. It was recently found that the relaxation frequency from actin of mutant α -actinin 4 was an order of magnitude lower than wild-type α -actinin 4. The resultant structural abnormality is believed to be the reason for proteinuria, renal dysfunction, and subsequent glomerulosclerosis. This has been supported in mouse studies; those with mutated α -actinin 4 with high affinity for F-actin have an FSGS-like phenotype, and mice deficient in α -actinin 4 have abnormal podocytes and develop ESRD.^{2,4} Patients with FSGS type 1 have variable age at onset and progression of renal disease.

The mutation responsible for FSGS type 2 was recently mapped to chromosome 11q21-22 in a New Zealand kindred and identified as transient receptor potential cation channel, subfamily C, member 6 (TRPC6).¹⁰ TRP channels are involved in various biologic processes including cell growth, mechanosensation, vasoregulation, and cation entry into cells. The P112Q

missense mutation involves the change of a proline (P) to a glutamine (Q) in a highly conserved region of the first ankyrin repeat of TRPC6 and results in a gain of function, with increased calcium influx presumably leading to glomerular dysfunction.^{2,4} This is an autosomal dominant disease that is manifested in the third and fourth decades of life. As many as 60% of affected individuals will progress to ESRD in 10 years. In contrast to known mutations that result in structural podocyte and slit diaphragm abnormalities, such as podocin, nephrin, and α -actinin 4, this is the first ion channel to be implicated as a cause of hereditary nephrotic syndrome and FSGS. The importance of TRPC6 in normal podocyte function has been further supported through discovery of *TRPC6* mutations in additional families with hereditary FSGS, two of which also result in increased calcium influx.¹¹ Furthermore, there is increased expression of wild-type TRPC6 in human proteinuric kidney diseases, animal models of kidney injury, and cultured podocytes exposed to complement and anti-podocyte antibodies.¹²

CD2-associated protein (CD2AP), a widely expressed protein originally identified through its interaction with CD2 in T lymphocytes, has been implicated in proteinuric renal disease. Cd2ap-deficient mice die of renal failure at 6 to 7 weeks of age. On histologic examination, foot process effacement and glomerulosclerosis are seen. Furthermore, mice expressing Cd2ap only in the podocyte are protected from kidney disease, suggesting that the proteinuria is due to podocyte-specific loss of Cd2ap. A corresponding disease in humans due solely to *CD2AP* mutations has not been clearly established to this point, but mutations in *CD2AP* in two adults with FSGS have been reported.¹³ CD2AP does localize to the slit diaphragm and has been shown to interact with nephrin and podocin (see Fig. 19.2).⁴ Therefore, it is plausible that a *CD2AP* mutation in humans could result in glomerular disease.

Mutations in *INF2*, the formin gene cause FSGS type 5. Using linkage analysis, a locus was identified on chromosome 14q32 and nine non-conservative missense mutations were identified in eleven families.^{13a} All mutations were located in the diaphanous inhibitory domain of *INF2*. Individuals in these

families present in early adolescence or adulthood with moderate proteinuria that progresses to ESRD. Some individuals also presented with microscopic hematuria and hypertension. Pathology shows typical FSGS, however on electron microscopy, prominent actin bundles were also noted within the foot processes. INF2 is a member of the formin family. These proteins regulate actin and accelerate actin polymerization. INF2 is widely expressed throughout the body and also in podocytes. When mutant INF2 constructs were transfected into podocytes, they exhibited different localization patterns than wild-type INF2. The exact pathogenetic mechanism of *INF2* mutations remains to be elucidated.

SYNDROMIC PROTEINURIC RENAL DISEASE

Denys-Drash and Frasier Syndromes

The Denys-Drash syndrome (DDS) and the Frasier syndrome are rare diseases that are manifested with early onset of congenital nephrotic syndrome and male pseudohermaphroditism (Fig. 19.5). Both are associated with the development of urogenital tumors: nephroblastoma or Wilms' tumor in DDS, and gonadoblastoma in Frasier syndrome. Patients with DDS have a high incidence of severe hypertension and rapid progression to ESRD. The glomerular lesion of DDS is diffuse mesangial sclerosis, and patients progress to ESRD by the age of 3 years. In Frasier syndrome, male pseudohermaphrodites typically present as phenotypic females with amenorrhea or nephrotic syndrome or both. The nephrotic syndrome may be slowly progressive (usually during 10 years); it is typically corticosteroid resistant, and the pathologic lesion is FSGS. The patients develop ESRD in their second and third decades of life, with most cases occurring at puberty. There are cases that present in much younger children.¹⁴ Rarely, an XX karyotype with a less severe phenotype may not be identified clinically as Frasier syndrome and presents only with renal disease.

The gene responsible for both Denys-Drash and Frasier syndromes has been localized to chromosome 11p13. The gene

Figure 19.5 Syndromic proteinuric renal diseases. AD, autosomal dominant; AR, autosomal recessive; FSGS, focal segmental glomerulosclerosis; GBM, glomerular basement membrane.

Syndromic Proteinuric Renal Diseases					
Disease	Inheritance	Gene	Protein	Clinical Presentation	Mechanism of Disease
Denys-Drash and Frasier syndromes	AD	<i>WT1</i>	WT1	Male pseudohermaphroditism, early nephropathy, and Wilms' tumor in Denys-Drash; later onset of nephropathy, FSGS, and gonadoblastoma in Frasier syndrome	Mutation in <i>WT1</i> results in abnormal urogenital development
Nail-Patella syndrome	AD	<i>LMX1B</i>	LMX1B	Skeletal, nails, eyes, and renal abnormalities; variable renal disease from benign proteinuria to nephrotic syndrome	Mutation in <i>LMX1B</i> results in abnormal regulation of podocyte genes
Pierson's syndrome	AR	<i>LAMB2</i>	Laminin β 2 chain	Microcoria, diffuse mesangial sclerosis, onset shortly after birth	Abnormal GBM due to mutations in adult form of laminin

Glomerular Diseases Associated with Abnormalities in Lipid Metabolism

Disease	Inheritance	Gene	Protein	Clinical Presentation	Mechanism of Disease
Lipoprotein glomerulopathy	Unknown	Unknown	Apolipoprotein E	Type III hyperlipidemia, nephrotic syndrome, renal failure, and deposition of lipid thrombi in glomerular capillaries	Abnormal lipid metabolism and deposition in various tissues
LCAT deficiency	AR	LCAT	LCAT	Anemia, corneal opacities, low HDL, elevated LDL, proteinuria, and progressive renal failure	Abnormal lipid metabolism and deposition in various tissues

Figure 19.6 Glomerular diseases associated with abnormalities in lipid metabolism. AR, autosomal recessive; HDL, high-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein.

product is the Wilms' tumor suppressor (WT1), which is a transcription factor involved in gonad and kidney development. WT1 seems to downregulate the expression of a number of genes involved in normal embryonic development of the urogenital system. Therefore, the decreased expression or lack of expression of WT1 seen in DDS and Frasier syndromes leads to the clinical manifestations of these diseases.^{2,14} This has been supported in mouse studies as *Wt1* knockout mice lack kidneys and gonads.¹⁴

Nail-Patella Syndrome

Nail-Patella syndrome (hereditary onycho-osteodysplasia; Fong syndrome) is an autosomal dominant disease involving abnormalities of the skeleton, nails, eyes, and kidneys. Affected patients have nail dysplasia, absence of or poorly developed patellas, dysplasia of the iliac horns and elbows, cataracts, glaucoma, and glomerulopathy.² The syndrome is discussed in detail in Chapter 46.

Pierson's Syndrome

In 1963, Pierson and colleagues described cases of congenital nephrotic syndrome with distinct eye abnormalities.¹⁵ Patients with Pierson's syndrome have hypoplasia of the ciliary body and iris resulting in fixed narrowing of the pupil (microcoria) as well as massive proteinuria at birth and rapid progression to ESRD. Most die before 2 months of age. Diffuse mesangial sclerosis exemplifies the renal pathology findings in Pierson's syndrome. The genetic defect has been isolated to chromosome 3p21, and the resultant mutation is in *LAMB2*, which codes for the laminin $\beta 2$ chain. *LAMB2* is present in the normal GBM, and the mutation results in abnormal formation of the GBM as well as abnormal differentiation of podocyte foot processes (see Fig. 19.2). *Lamb2* knockout mice demonstrate congenital nephrosis with abnormalities of the retinal and neuromuscular junctions.^{2,15}

Galloway-Mowat Syndrome

In 1968, two siblings with nephrotic syndrome, hiatal hernia, and abnormal development of the central nervous system were described by Galloway and Mowat.¹⁶ By 2001, 31 more patients with similar clinical features had been described. The Galloway-Mowat syndrome is inherited in an autosomal recessive pattern. The currently recognized clinical features include microcephaly, abnormal cerebral gyral patterns, seizures, psychomotor retardation,

Figure 19.7 Lipoprotein glomerulopathy. Dilated capillary lumina containing a pale-stained, mesh-like or granular substance. (Trichrome stain; magnification $\times 260$.) (Modified from reference 23.)

cranial dysmorphism, and glomerulopathy. The renal disease generally presents as the nephrotic syndrome within the first few months of life with rapid progression to ESRD. Most affected children die before the age of 6 years. Based on the time of biopsy, various renal findings have been reported by light microscopy. These include diffuse mesangial sclerosis, mesangial proliferation, FSGS, cystic microdilation of tubules, and normal-appearing glomeruli. By electron microscopy, irregular thickening of the GBM and effacement of podocyte foot processes are seen. The genetic abnormality has not been found, but because of multiple reports of the same disease in siblings, it is presumed to be a familial disorder.¹⁷

Glomerulopathy Associated with Abnormalities in Lipid Metabolism

Nephrotic-range proteinuria, edema, hypoalbuminuria, lipiduria, and hyperlipidemia are hallmarks of the nephrotic syndrome. Yet, the hyperlipidemia is thought to be a consequence of urinary losses of cholesterol and albumin, resulting in increased hepatic synthesis of low-density lipoproteins, very low density lipoproteins, and lipoprotein(a).¹⁸ However, some rare proteinuric kidney diseases are due to abnormal metabolism of lipids, resulting in deposition of lipids in glomeruli and subsequent nephrotic syndrome (Fig. 19.6).

Lipoprotein glomerulopathy presents in adulthood with proteinuria and often nephrotic syndrome with rapid progression to renal failure. Light microscopy reveals extensive deposition of laminated lipid thrombi in glomerular capillaries (Fig. 19.7). The

lipid deposits contain apolipoproteins A, B, and E (see Fig. 19.2). Because of studies of affected kindreds, particularly in Japan, it is thought to be a hereditary disease. The mutation is believed to be in apolipoprotein E as these patients also have a type III hyperlipidemia, characterized by elevated intermediate-density lipoproteins and apolipoprotein E. Treatment with lipid-lowering drugs, such as fibric acid derivatives, has shown some benefit.¹⁹

Lecithin-cholesterol acyltransferase (LCAT) deficiency is an autosomal recessive disease characterized by anemia, corneal opacities, low high-density lipoprotein level, elevated low-density lipoprotein level, proteinuria, and often nephrotic syndrome with progressive renal failure. The disease generally presents in adulthood and is slow in onset. Light microscopy reveals irregular thickening of the glomerular capillaries with “vacuolization” of the capillary basement membranes due to lipid droplets (Fig. 19.8). This is the “foamy” appearance characteristic of LCAT deficiency. Mesangial and basement membrane electron-dense lamellar structures are also seen and are unique

Figure 19.8 Lecithin-cholesterol acyltransferase deficiency. Note the irregular thickened glomerular capillary walls containing clear vacuoles, which are characteristic of the lesion. (Periodic acid-Schiff; magnification ×1000.) (Modified from reference 23.)

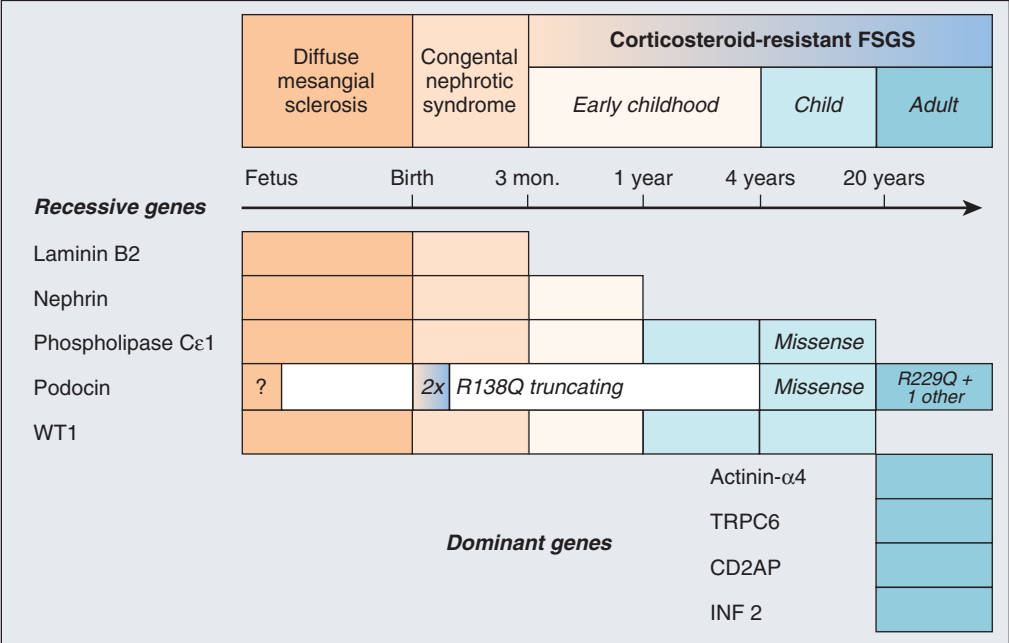

Figure 19.9 Inheritance patterns of nephrotic syndromes. Autosomal recessive diseases generally present early in life as diffuse mesangial sclerosis or congenital nephrotic syndrome. In early childhood, mutations in genes encoding nephrin, podocin, WT1, and phospholipase Cε1 will also cause disease. Podocin mutations result in disease at different times on the basis of the particular mutation, with disease in young adults as well (see text). Autosomal dominant conditions present later in life and have been described in families with FSGS with mutations in genes encoding α-actinin 4 and TRPC6. CD2AP mutations are suspected but have not been described as a sole cause of disease in humans. FSGS, focal segmental glomerulosclerosis. (Modified from reference 8.)

to this disorder. The genetic mutation is in the *LCAT* gene on chromosome 16q22. LCAT deficiency responds poorly to treatment.²⁰

GENETIC TESTING

Children with a family history of corticosteroid-resistant nephrotic syndrome or after failure of an initial treatment course of corticosteroids should undergo renal biopsy and be considered for genetic testing. Mutations in the recessive genes that encode nephrin (*NPSH1*), podocin (*NPFS2*), phospholipase Cε1 (*PLCE1*), WT1 (*WT1*), and laminin β2 (*LAMB2*) cause proteinuric renal disorders in children. *NPFS1*, *NPFS2*, *LAMB2*, and *WT1* mutations are responsible for 85% of glomerular disease seen in the first 3 months of life and 66% in the first year, and these certainly should be the first tests sent in screening of children for inherited conditions.⁸ Diffuse mesangial sclerosis is seen with mutations in *NPFS1*, *PLCE1*, *LAMB2*, and *WT1*. FSGS is seen with mutations in *NPFS2*. The Galloway-Mowat syndrome can have either diffuse mesangial sclerosis or FSGS-like changes, but the genetic defect is not known. Further testing will be determined by the patient’s presentation. In most cases of syndromic disease, the clinical characteristics will dictate which genetic tests are necessary and may narrow the analysis to one or two genes. For example, in a patient with pseudohermaphroditism and renal disease, *WT1* mutations are likely, and *LAMB2* testing can be done in those with congenital nephrotic syndrome and microcoria.

Inherited nephrotic syndrome in adults generally presents as FSGS and is believed to be responsible for up to 18% of cases identified in those older than 18 years.¹ Genetic testing should be considered when there is a strong family history of disease. Autosomal dominant disease will exist in multiple family members in successive generations, and there will be male-to-male transmission. Known gene mutations to investigate include *ACTN4* and *TRPC6*. Young adults may have FSGS due to a combination of mutations in podocin, one of which is the R229Q mutation. This may be more difficult to identify because the inheritance pattern will not be as apparent (Fig. 19.9).⁸

CLINICAL MANAGEMENT OF INHERITED NEPHROTIC SYNDROME

ACE inhibitors and angiotensin receptor blockers (ARBs) are appropriate medications for children with corticosteroid-resistant nephrotic syndrome. Cyclophosphamide, cyclosporine, tacrolimus, rituximab, and mycophenolate have been used with limited success in small studies. However, given the preponderance of side effects with these medications, they are generally not used in children.²¹

Adults with corticosteroid-resistant hereditary FSGS should be treated with ACE inhibitors and ARBs. Lipid-lowering medications are also recommended as adults with nephrotic syndrome have hyperlipidemia and may have increased risk of cardiovascular disease. Cyclosporine is generally used for initial treatment in FSGS not responsive to corticosteroids and may be appropriate in inherited forms as well. Mycophenolate can be substituted in those who do not respond to cyclosporine or have a contraindication to its use. Limited evidence is available for use of tacrolimus or sirolimus.²²

As these disorders are due to inherited abnormalities in renal developmental or structural proteins, there should not be recurrence of the original condition after transplantation because the donor kidney presumably is from a patient without a genetic renal disease. However, the reported recurrence rate of nephrotic syndrome in those with inherited disorders is misleading as chronic allograft nephropathy can present with an FSGS-like phenotype. Similarly, reports of recurrence in patients with podocin mutations exist, but given the complex inheritance pattern, with some diseases manifesting in children and others in adults, it is difficult to interpret. More recent data suggest a recurrence rate of nephrotic syndrome in the transplant in those with *NPSH2* mutations to be very low.⁸ Reappearance of the nephrotic syndrome in congenital nephrotic syndrome of the Finnish type is not truly a “recurrence” but thought to be due to anti-nephrin autoantibodies and not a *de novo* nephrin mutation in the transplanted kidney. Therefore, transplantation is not discouraged in those with congenital nephrotic syndromes, and their postsurgery management should not differ from usual clinical care; in fact, there are data to suggest that those with inherited nephrotic syndromes and FSGS may have better transplant survival outcomes than in those with idiopathic disease.

Membranous Nephropathy

William G. Couser, Daniel C. Cattran

DEFINITION

Membranous nephropathy (MN) is a glomerular disease in which immune deposits of IgG and complement components develop predominantly or exclusively beneath podocytes on the subepithelial surface of the glomerular capillary wall. Deposit formation is associated with a marked increase in glomerular permeability to protein, which is manifested clinically as nephrotic syndrome.¹ The disease occurs in association with a variety of conditions, some of which are likely to be causal and some of which probably represent only associations (Fig. 20.1).² However, most occurrences (two thirds) are without obvious initiating events. Idiopathic MN is the most common cause of primary nephrotic syndrome in older (>60 years) Caucasian adults and is rare in children.³

The term *membranous* refers to thickening of the glomerular capillary wall by light microscopy, but the entity now referred to as MN was defined when immunofluorescence and electron microscopy became routine tools in the study of renal biopsy specimens in the 1960s. These techniques demonstrated diffuse, finely granular immune deposits in the subepithelial space that are now regarded as pathognomonic of MN. Consequently, MN is a pathologic diagnosis made when glomeruli exhibit these deposits without associated hypercellularity or inflammatory changes.¹

ETIOLOGY AND PATHOGENESIS

Etiology

The frequent occurrence of MN in autoimmune disorders (such as lupus and type 1 diabetes) and its remarkable similarity to a lesion induced in rats with antibody to antigens expressed on the foot processes of glomerular podocytes have fueled speculation that the disease is caused by deposits of autoantibody to fixed components of the podocyte membrane.^{2,4} A large number of agents appear to be capable of initiating MN in genetically susceptible individuals (see Fig. 20.1). These include viruses such as hepatitis B (HBV) and hepatitis C (HCV); drugs, including gold, penicillamine, and nonsteroidal anti-inflammatory drugs (NSAIDs); environmental toxins, such as hydrocarbons and formaldehyde; and a variety of chronic immune disorders, such as lupus, thyroiditis, graft-versus-host disease, anti-glomerular basement membrane (anti-GBM) and antineutrophil cytoplasmic antibody (ANCA)-positive crescentic glomerulonephritis (GN), and the chronic immune response to renal allografts. In about two thirds of patients, however, no obvious etiologic agent or condition can be identified.

Mechanisms of Immune Deposit Formation

Regardless of the initiating events, MN appears to be mediated primarily by the Th2 humoral immune response, which leads to formation of deposits of IgG and complement on the outer surface of the glomerular capillary wall. Experimental evidence suggests that such deposits are produced by local or *in situ* immune complex formation involving antigens that could be exogenous or endogenous. Subepithelial immune complex deposits can form in three ways.⁴ Antibodies can bind to exogenous antigens that localize on the subepithelial surface because of their cationic charge and small size; second, antigens and antibodies can be trapped as immune complexes on the inner surface of the capillary wall, dissociate, traverse the glomerular basement membrane (GBM), and reform in the subepithelial space; and finally, the antigens could be endogenous constituents of a fixed subepithelial structure, such as a podocyte membrane protein.^{2,4} The absence of deposits at sub-endothelial (and mesangial) sites in idiopathic MN as well as the ability to exactly replicate the clinical and pathologic features of MN in rats with anti-podocyte antibodies (Heymann nephritis) strongly favors the third, or autoimmune, mechanism. In the Heymann nephritis models, the antigens responsible are components of the Heymann nephritis antigenic complex: a large (516-kd) glycoprotein, called megalin, bound to a smaller receptor-associated protein expressed in the clathrin-coated pits of the podocyte foot processes.⁴ Whereas antibodies to small antigenic determinants on both molecules can form subepithelial immune complex deposits, additional antigen-antibody systems involving an unidentified glycolipid antigen that activates complement as well as antibodies that neutralize complement regulatory proteins are required to induce proteinuria in animals.^{2,4} Once formed, these complexes of antigen and antibody are capped and shed from the cell surface, where they bind to underlying GBM, resist degradation, and persist for weeks or months as immune deposits detectable by immunofluorescence and electron microscopy (Fig. 20.2; see also Figs. 20.6 and 20.7).

Confirmation that a similar mechanism may be operative in idiopathic MN in humans has come from two sources. Several cases of congenital MN have been shown to be mediated by an antibody to neutral endopeptidase (NEP), an antigen expressed on the podocyte membrane.² In these cases, mothers with a hereditary absence of NEP become sensitized during pregnancy and passively transfer anti-NEP IgG to the infant, who is born with congenital nephrotic syndrome caused by MN through an alloimmune mechanism.² NEP has also been documented in glomerular deposits in some patients with *de novo* MN after renal transplantation but not in adult patients with idiopathic MN.² A particularly promising study in adults has identified antibody to

Conditions and Agents Associated with Membranous Nephropathy		
Groups	Common	Uncommon
Immune diseases	Systemic lupus erythematosus, diabetes mellitus	Rheumatoid arthritis, Hashimoto's disease, Graves' disease, mixed connective tissue disease, Sjögren's syndrome, primary biliary cirrhosis, bullous pemphigoid, small bowel enteropathy syndrome, dermatitis herpetiformis, ankylosing spondylitis, graft-versus-host disease, Guillain-Barré syndrome, bone marrow and stem cell transplantation, anti-GBM and ANCA-positive crescentic GN
Infectious or parasitic diseases	Hepatitis B	Hepatitis C, syphilis, filariasis, hydatid disease, schistosomiasis, malaria, leprosy
Drugs and toxins	Gold, penicillamine, NSAIDs	Mercury, captopril, formaldehyde, hydrocarbons, bucillamine agents
Miscellaneous	Tumors, renal transplantation	Sarcoidosis, sickle cell disease, Kimura disease, angiofollicular lymph node hyperplasia

Figure 20.1 Conditions and agents associated with membranous nephropathy. The list excludes conditions for which only a single case has been reported or the lesions were atypical of membranous nephropathy. (Modified with permission from reference 5.)

Figure 20.2 Events in a rat model of membranous nephropathy. Immune deposit formation, C5b-9 insertion, and podocyte activation lead to proteinuria (see text).

phospholipase A₂ receptor (PLAR), another antigen expressed on podocyte foot processes, in a majority of patients with active idiopathic MN and correlated antibody levels with disease activity and response to therapy.⁶ This antibody has also been eluted from glomeruli of patients with MN. Anti-PLAR antibody has been identified only in primary idiopathic MN and not in MN secondary to other causes.

Mechanism of Glomerular Injury

Based entirely on studies in animal models, the mechanism of glomerular damage sufficient to cause proteinuria appears to

involve sublytic effects of complement C5b-9 (a multimer comprising several complement components and also known as the membrane attack complex) on the podocyte,^{4,7} although complement-independent mechanisms of proteinuria have also been described in some studies.⁸ When complement activation occurs at the site of deposit formation, it leads to cleavage of C5, which generates C5a and C5b. C5b combines with C6 to form a lipophilic complex that inserts into the lipid bilayer of the podocyte, where C7, C8, and multiple C9 molecules are added to create a pore-forming complex, C5b-9. The podocyte is resistant to lysis and endocytoses the C5b-9, transporting the complex intracellularly in multivesicular bodies and extruding it into the

urinary space. However, the membrane insertion of C5b-9, although insufficient to cause apoptosis or cell lysis, does induce cell activation and signal transduction. This results in increased production of multiple potentially nephritogenic molecules, including oxidants, proteases, cytokines, growth factors, vasoactive molecules, and extracellular matrix.^{4,7} Current evidence is strongest for the role of podocyte-derived oxidants in producing the GBM damage that leads to increased protein filtration in MN. When antibody deposition, deposit formation, and complement activation are occurring, increased urinary excretion of C5b-9 and viable podocytes occurs.⁹

Consequences of Injury Induced by C5b-9

The glomerular injury mediated by C5b-9 induces a nonselective proteinuria through loss of both the size- and the charge-selective properties of the glomerular capillary wall. The subsequent reduction in glomerular filtration rate (GFR) that occurs in progressive MN has both glomerular and interstitial components. In the glomerulus, there is thickening of the GBM resulting from overproduction of several different extracellular matrix molecules that accumulate between and around the immune deposits to form the subepithelial “spikes” characteristic of this disease when a biopsy specimen is studied with silver methenamine staining (Fig. 20.5C). This appears to occur in part through upregulation of podocyte production of transforming growth factor (TGF) β 2 and β 3 as well as increased expression of TGF- β receptors in response to C5b-9.⁷ Podocyte cell number decreases because of apoptosis and cell detachment as the glomerulus expands secondary to increased pressures and flows.⁹ The podocyte itself has limited ability to proliferate and to cover denuded areas of GBM because of C5b-9-induced overexpression of cyclin kinase inhibitors and cell cycle arrest, and the consequent podocytopenia leads to progressive glomerulosclerosis. In the interstitium, there is an increased macrophage infiltrate and overproduction of matrix by interstitial myofibroblasts, leading to interstitial fibrosis,^{3,10} a response common to all nonselective proteinuric disorders (see also Chapter 75). When nephrotic-range proteinuria persists, the consequence is glomerular sclerosis as well as interstitial fibrosis and progression to renal failure at a rate that is usually directly related to both the magnitude and the duration of increased protein filtration.

EPIDEMIOLOGY

MN is uncommon in children; it usually accounts for less than 5% of pediatric patients undergoing biopsy for nephrotic syndrome.³ About 30% of all biopsy specimens for primary nephrotic syndrome reveal MN in adults and about 50% in older Caucasian adults.¹

There is some variation in these figures among different countries, with slightly lower numbers in the United Kingdom and higher numbers in Greece and Macedonia. The United States Renal Data System in 2008 reported the incidence of end-stage renal disease (ESRD) due to MN from 2002 to 2006 at about 460 patients per year, which represents 0.4% of the total ESRD population.¹¹ Because only 20% of all patients with MN progress to ESRD, the real incidence of MN is approximately 2300 patients per year in the United States or about 8 patients per million population per year.

There is a threefold increased risk for MN in Caucasian patients with HLA-DR3, and associations with HLA-B8 and HLA-B18 have also been reported.¹ HLA-DR5, in addition to

Clinical Features of Membranous Nephropathy

Rare in children – <5% of total cases of nephrotic syndrome
Common in adults – 15% to 50% of total cases of nephrotic syndrome, depending on age. Increasing frequency after age 40 years.
Males > females in all adults groups
Caucasians > Asians > African-Americans > Hispanics
Nephrotic syndrome in 60% to 70%
Normal or mildly elevated BP at presentation
“Benign” urinary sediment
Non-selective proteinuria
Tendency to thromboembolic disease (DVT, RVT, PE)
Secondary causes: infection, drugs, neoplasia, systemic lupus erythematosus

Figure 20.3 Clinical features of membranous nephropathy. BP, blood pressure; DVT, deep venous thrombosis; RVT, renal vein thrombosis; PE, pulmonary embolism.

HLA-DR3, increases the risk of progression in Caucasians. In Japan, MN is associated with HLA-DR2. Some Caucasian patients have a deletion of C4 with the HLA-B8-DR3 haplotype. Rare examples of familial MN have also been reported, usually presenting in siblings.³

CLINICAL MANIFESTATIONS

MN affects patients of all ages and races but is more common in men than in women by 2:1 (Fig. 20.3). Idiopathic MN is most often diagnosed in middle age, with the peak incidence during the fourth and fifth decades of life. MN in childhood is more often secondary (such as due to hepatitis B virus). Seventy percent to 80% present with the nephrotic syndrome.^{12,13} The remaining 20% to 30% present with subnephrotic asymptomatic proteinuria (<3.5 g/24 h). Proteinuria is nonselective. Microscopic hematuria is common (30% to 40%), but macroscopic hematuria and red cell casts are rare and suggest a different glomerular pathologic process. In idiopathic MN, serum complement levels are normal despite evidence of intraglomerular complement activation, and serologic markers such as antinuclear antibodies, ANCA, and rheumatoid factor are normal or absent. At the time of diagnosis, only 10% to 20% have hypertension. Renal function is usually normal at presentation, with only a small fraction (<10%) presenting with renal impairment (Fig. 20.4). These presenting features can be modulated by age or preexisting hypertension; tubulointerstitial and vascular changes on biopsy may be related to these factors rather than to the severity of the MN.¹⁴ This is supported by recent evidence that age *per se* does not influence the rate of progression in MN but does influence the GFR at presentation. Other complications related to the nephritic syndrome include dyslipidemia, which probably contributes to the increased cardiovascular risk, and a high prevalence (10% to 40%) of thromboembolic events including renal vein thrombosis.

Diagnosis and Management of Patients with Membranous Nephropathy	
Patient Groups	Test
All patients	Blood pressure Renal function (serum creatinine and creatinine clearance) Urine protein excretion (24-h urine or urine protein to creatinine ratio) Serum albumin Serum cholesterol Urinalysis Renal biopsy
Associated disease	Hepatitis B (HBs antigen) Hepatitis C (HCV antibody) Antinuclear antibody (ANA), anti-double-stranded DNA (the hallmark of systemic lupus erythematosus) Complement C3, C4 (usually normal in idiopathic membranous nephropathy)
Selected Patients	
With suspected thromboembolic events, flank pain, hematuria, acute renal failure	Renal venous Doppler ultrasound Contrast CT, MRI
With sudden decrease in renal function, development of active urine sediment	Anti-GBM antibody ANCA Assess for interstitial nephritis
Suggestive symptoms or >50 years of age	Cancer screening (see text)

Figure 20.4 Diagnosis and management of patients with membranous nephropathy. ANCA, antineutrophil cytoplasmic antibody; anti-GBM, anti-glomerular basement membrane; CT, computed tomography; MRI, magnetic resonance imaging.

PATHOLOGY

The earliest pathologic feature of MN relates to the initial formation of subepithelial immune complexes of IgG and complement along the outer surface of the capillary wall in which glomeruli appear histologically normal and therefore may be mistaken for minimal change nephrotic syndrome if only light microscopy is performed. After immune complex formation, changes occur first in the podocyte, then in glomerular barrier function leading to proteinuria, then in the renal interstitium (probably as a consequence of the proteinuria), and finally in the GBM itself, which becomes thickened (membranous) through the accumulation of additional matrix material along the outer surface, often in an irregular or spike-like pattern.^{2,13}

Light Microscopy

In the earliest stages of the disease, the glomeruli and interstitium appear normal by light microscopy, and the diagnosis is made by immunohistology and electron microscopy (Fig. 20.5A). The next stage of MN involves a homogeneous thickening of the capillary wall, seen with light microscopy in sections stained with hematoxylin and eosin or with periodic acid–Schiff reagent (Fig. 20.5B). By silver methenamine staining, early projections of the GBM between deposits may be detected in a characteristic spike-like configuration (see Fig. 20.5C). Later lucencies may develop in the GBM as immune deposits are resorbed, resulting in some areas of the GBM appearing as double contours by silver methenamine staining.

Leukocyte infiltration is absent in glomeruli in MN, probably because chemotactic products of complement activation follow filtration forces into the urinary space rather than diffusing backward into the capillary lumen, and the intervening GBM prevents immune adherence mechanisms from being operative.

Although similar deposits at other sites may induce proliferation of glomerular endothelial and, particularly, mesangial cells, podocytes *in vivo* seem terminally differentiated and rarely proliferate.⁶ As a result, the pathologic lesion of MN is characterized only by changes in podocytes and basement membrane without any associated glomerular hypercellularity.

The podocyte response to this form of injury includes effacement of foot processes visible only by electron microscopy. In general, there are no visible mesangial or endothelial cell abnormalities. The presence of significant mesangial hypercellularity suggests immune deposit formation in the mesangium and is more consistent with a secondary MN, such as class V lupus nephritis (see Chapter 25). In some patients with heavy proteinuria and progressive disease, glomeruli exhibit reduced podocyte numbers and areas of focal sclerosis that are similar to the appearance of idiopathic focal segmental glomerulosclerosis (FSGS) (see Chapter 18). These patients often have a more rapidly progressive course and a poor response to therapy. These sclerotic lesions may be a consequence of glomerular hypertrophy accompanied by an inability of the terminally differentiated podocytes to proliferate,⁷ leading to areas of denuded GBM, attachment to Bowman's capsule, and subsequent capillary collapse (see Chapter 75).

As in all glomerular diseases, tubulointerstitial injury is common and correlates with both the renal function and the level of proteinuria. Some studies suggest that the long-term outcome correlates in general with the severity of the tubulointerstitial damage (see Chapter 75).

Immunohistology

The pattern of IgG staining in MN is characteristic and easily recognizable by immunohistology (Fig. 20.6). Positive staining for IgG marks the finely granular subepithelial deposits, which

Figure 20.5 Light microscopy in membranous nephropathy. **A**, Early MN: a glomerulus from a patient with severe nephrotic syndrome and early MN exhibiting normal architecture and peripheral capillary basement membranes of normal thickness. (Silver methenamine; magnification $\times 400$.) **B**, Morphologically advanced MN: uniform increase in the thickness of the glomerular capillary walls throughout the glomerulus without any increase in glomerular cellularity. (Periodic acid–Schiff; magnification $\times 400$.) **C**, Morphologically more advanced MN (same patient as in **B**): discrete spikes of matrix emanating from the outer surface of the basement membrane (arrow) indicative of advanced MN are revealed by silver methenamine stain. (Magnification $\times 400$.) (Courtesy C. E. Alpers.)

Figure 20.6 Immunofluorescence in membranous nephropathy. A glomerulus with diffuse, finely granular deposition of IgG along the outer surface of all capillary walls. The antibody is believed to represent auto-antibody directed at some constituent of the podocyte membrane. (Original magnification $\times 400$). (Courtesy C. E. Alpers.)

are present on the outer surface of all capillary walls.² The predominant IgG subclass in idiopathic MN is IgG4. Positive staining for IgG1 or IgG3, IgA, or IgM or significant staining in the glomerular mesangium suggests lupus as an underlying mechanism. Complement C3 is also present in about 50% of patients and usually reflects staining for C3c, a breakdown product of C3b that is rapidly cleared. Consequently, positive C3 staining probably reflects active, ongoing immune deposit formation and complement activation at the time of the biopsy, whereas the absence of C3 suggests that the process of forming deposits has ceased. When it is looked for, staining for C5b-9 is generally present as well, consistent with the proposed pathogenetic role of C5b-9 in this disease.^{2,7} C1 and C4 are often absent, indicating activation of complement primarily through the alternative pathway as a consequence of podocyte damage or downregulation of complement regulatory proteins expressed on the podocyte membrane.

Electron Microscopy

The presence of subepithelial electron-dense deposits by electron microscopy parallels IgG staining. In idiopathic MN, immune deposit formation occurs in a subepithelial distribution, and deposits are not seen in mesangial or subendothelial sites. These deposits in early stages of the disease process are homogeneous and may even be confluent in some areas with overlying podocyte foot process effacement and little change in the underlying GBM (stage I). As the disease persists, there is projection of basement membrane material up between the deposits to form subepithelial spikes that can be detected by light microscopy with use of a silver methenamine stain and are easily visible by electron microscopy (stage II; Fig. 20.7A). Later, the spikes extend and the deposits may become surrounded by new basement membrane-like material (stage III; Fig. 20.7B). In stage IV disease, the basement membrane is overtly thickened, the

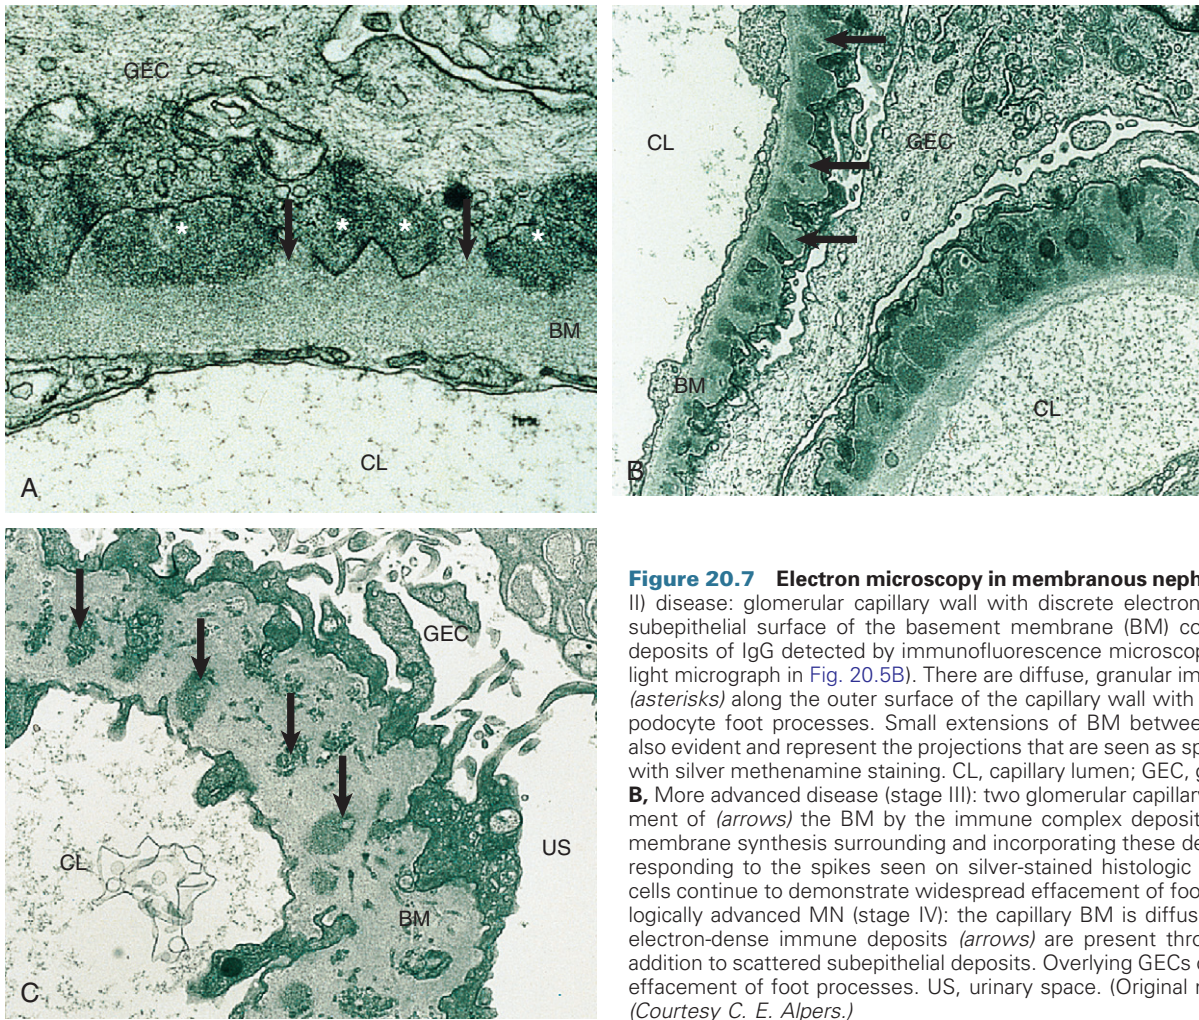

Figure 20.7 Electron microscopy in membranous nephropathy. **A**, Early (stage II) disease: glomerular capillary wall with discrete electron-dense deposits on the subepithelial surface of the basement membrane (BM) corresponding to granular deposits of IgG detected by immunofluorescence microscopy (corresponding to the light micrograph in Fig. 20.5B). There are diffuse, granular immune complex deposits (asterisks) along the outer surface of the capillary wall with effacement of overlying podocyte foot processes. Small extensions of BM between deposits (arrows) are also evident and represent the projections that are seen as spikes by light microscopy with silver methenamine staining. CL, capillary lumen; GEC, glomerular epithelial cell. **B**, More advanced disease (stage III): two glomerular capillary loops showing involvement of (arrows) the BM by the immune complex deposition. There is prominent membrane synthesis surrounding and incorporating these deposits into the BM (corresponding to the spikes seen on silver-stained histologic preparations). Overlying cells continue to demonstrate widespread effacement of foot processes. **C**, Morphologically advanced MN (stage IV): the capillary BM is diffusely thickened; scattered electron-dense immune deposits (arrows) are present throughout its thickness in addition to scattered subepithelial deposits. Overlying GECs continue to demonstrate effacement of foot processes. US, urinary space. (Original magnifications $\times 18,000$.) (Courtesy C. E. Alpers.)

deposits incorporated in it become more lucent, and the spikes are less apparent (Fig. 20.7C). The extent to which individual patients will exhibit these stages as sequential changes depends on the duration of the underlying immunopathologic process and its severity. Although these changes clearly reflect the severity and duration of disease, they do not correlate well with clinical manifestations or outcome.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When the initial presentation includes the nephrotic syndrome, the differential diagnosis includes minimal change disease (MCD), FSGS, membranoproliferative glomerulonephritis (MPGN) type I and dense deposit disease (DDD), amyloidosis, light-chain deposition disease, lupus nephritis, and diabetic nephropathy. In the 20% to 25% whose initial presentation is asymptomatic proteinuria, the differential is even more extensive.¹⁵ Whereas clinical clues may increase the likelihood for one etiology over another, the etiology of the nephrotic syndrome is best determined by renal biopsy.

Patients presenting with clinical features including less than 3.5 g/day of proteinuria, no red cell casts, no hypertension, normal renal function, and no systemic features suggestive of a secondary cause have a relatively benign prognosis. If no renal biopsy is performed, these patients must be monitored because

up to 50% may later develop nephrotic-range proteinuria, the majority within the first 2 years of presentation.

Secondary MN represents 20% to 30% of all cases (see Fig. 20.1); the most common causes are systemic lupus, hepatitis B, malignant neoplasms, and drugs. In addition to a careful history and physical examination, appropriate laboratory evaluation for potential secondary causes should include a complement profile, antinuclear antibodies, hepatitis serology, chest radiography, stool testing for occult blood, mammography in women, and prostate-specific antigen testing with or without digital rectal examination in men. In women between the ages of 20 and 50 years, a high index of suspicion is warranted for underlying lupus.¹ This diagnosis can be particularly difficult to make because the majority of these patients have no systemic symptoms and serologic markers of systemic lupus erythematosus are often absent. Membranous lupus accounts for 8% to 27% of cases of lupus nephritis (see Chapter 25).¹

In adults, regardless of age, malignant neoplasia is the most common secondary cause of MN (see Fig. 20.1). The colon, kidney, and lung are the most common primary sites, and in some patients, the tumor may not have been discovered at the time the patient presents with renal disease. Although it is hypothesized that antigens derived from the tumor account for deposit formation and injury in glomeruli, very few tumor-related antigens have actually been demonstrated.

Hepatitis B (HBV)-associated MN is also a very common secondary cause in countries where HBV is endemic. It can affect both adults and children who are chronic carriers of HBV (positive HBsAg, HBcAg, and usually HBeAg).¹⁶ This can occur with or without a history of overt liver disease. In children, HBV-associated MN most commonly presents as the nephrotic syndrome and usually follows a benign course.³ In adults, progressive renal impairment is a more common outcome. Hypocomplementemia is present in approximately 50% of cases of MN with HBV.

MN secondary to drugs usually resolves after discontinuation of the offending agent.^{17,18} The time to resolution, however, varies significantly from as early as 1 week (e.g., for NSAIDs) to several years for gold or D-penicillamine. Many other renal disorders have been seen in association with or superimposed on MN, including IgA nephropathy, FSGS, crescentic GN (anti-GBM disease, ANCA vasculitis), acute interstitial nephritis, and diabetic nephropathy.

CLINICAL COURSE, OUTCOMES, AND COMPLICATIONS

The clinical course of MN varies widely. Spontaneous remissions in proteinuria have been reported in up to 30% of cases. As the severity of proteinuria at presentation increases, the frequency of spontaneous remission appears to decrease. Female sex and lower grade (non-nephrotic) proteinuria at presentation are the only two features associated with a higher likelihood of spontaneous remission.¹⁹ This is likely to produce a bias in renal survival because the majority of studies reporting 10-year outcomes in untreated patients have included those with subnephrotic proteinuria (<3.5 g/24 h). For example, one study reported a 72% renal survival at 8 years for 100 untreated patients, but 37% of the patients were non-nephrotic at presentation and more than 50% had less than 5 g/day.²⁰ In addition, deaths were excluded from the kidney survival analysis. Even so, there was a 25% ESRD rate by 8 years and almost 50% by 15 years.

In summary, although the majority of MN patients do reasonably well long term, MN is still the second or third leading cause of ESRD among subjects with primary GN. What is still missing from most MN survival data is the much higher than expected (standard incidence ratio) death rate due to cardiovascular disease or thromboembolic events seen in patients who remain nephrotic. When another renal condition is superimposed on MN, there is often an associated acceleration in the rate of deterioration in renal function. The most common conditions to consider in this setting are drug-induced interstitial nephritis, superimposed anti-GBM disease, and renal vein thrombosis.

Predictors of Poor Outcome

Given the wide variation in the natural history of MN and the current lack of a serologic marker of disease activity, other clinical markers that predict individual outcome would be valuable. A list of factors associated with progression and the strength of those associations is presented in Figure 20.8. Both age and sex influence outcome, with male sex and increasing age associated with a higher risk for renal failure. However, both have limitations.²¹ Age seems to be related to the underlying pathologic process at the time of presentation rather than to the severity of disease because it does not influence rate of deterioration in function, and the sex of the patient seems more closely related

Factors Associated with Worse Renal Survival in Membranous Nephropathy

Factors	Predictor	Positive Predictive Value %
Clinical features		
Age	Older > younger	43
Sex	Male > female	30

to the severity of proteinuria at presentation rather than representing an independent risk factor for progression. The severity of chronic changes seen on the biopsy specimen (i.e., degree of glomerulosclerosis, tubulointerstitial fibrosis, and vascular disease) has been associated with a poor prognosis but more closely reflects initial GFR than the subsequent rate of renal functional deterioration.¹⁴ Other pathologic features, including the percentage of glomeruli with glomerulosclerosis and the configuration of the immune deposits (synchronous/single stage or heterogeneous/multistage) on electron microscopy, have also been suggested as predictors of both outcome and response to treatment but have not been validated in prospective studies. The degree of renal impairment at presentation has also been found to correlate with long-term renal survival, but a better and more sensitive predictor of long-term prognosis is the ongoing rate of renal function loss as measured by the decline of creatinine clearance over time.

One of the best models to calculate risk takes into consideration the initial creatinine clearance, the slope of the creatinine clearance during a fixed period, and the lowest level of proteinuria during that observation period (Fig. 20.9).²² This risk score assessment has a reported sensitivity of 60% to 89%, specificity of 86% to 92%, and overall accuracy from 79% to 87%. The model predicts that patients with a normal creatinine clearance at presentation that remains stable during 6 months and with persistent proteinuria of less than 4 g/24 h have less than a 5% chance of progression, and only conservative treatment is recommended. In contrast, those patients with proteinuria that remains

Renal Disease Risk Categories		
Low Risk	Medium Risk	High Risk
Normal serum creatinine and creatinine clearance plus proteinuria <4 g/day over six months of observation	Normal or near normal creatinine clearance and persistent proteinuria ≥ 4 g/day to ≤ 8 g/day over 6 months despite maximum conservative treatment	Deteriorating renal function and/or persistent proteinuria ≥ 8 g/day for <3–6 months of observation

Figure 20.9 Risk categories of renal disease progression in membranous nephropathy.

above 4 g but less than 8 g/24 h during the same time frame have a 55% probability for development of chronic renal impairment; and those with persistent proteinuria above 8 g/24 h have a 66% to 80% probability of progression to chronic kidney disease within 10 years (see Fig. 20.9). Recently, other biomarkers including urinary α_1 -microglobulin, β_2 -microglobulin, IgM, and IgG have also been strongly associated with progression.²³ These markers measured together at a single time point have a higher positive predictive value than proteinuria alone, but none has yet been validated in an independent data set.

Relapse After Complete Remission or Partial Remission

Relapse from a complete remission occurs in approximately 25% to 40% of MN cases with an unpredictable time line. Relapses have been reported up to 20 years after the primary remission. However, the great majority of patients will relapse only with subnephrotic-range proteinuria and will maintain stable long-term kidney function with conservative management alone.¹⁹ In contrast, the relapse rate is as high as 50% in those achieving only a partial remission. Achievement of either a complete or partial remission, however, significantly slows progression and increases renal survival. A recent review of 348 nephrotic MN patients documented a 10-year renal survival in patients with a complete remission of 100%; with partial remission, 90%; and with no remission, only 45%.²⁴

TREATMENT

Nonimmunosuppressive Therapy

Conservative management is directed at control of edema, hypertension, hyperlipidemia, and proteinuria and is similar to that used for nephrotic syndrome of any etiology (see Chapter 15). Blood pressure control is important for both renal and cardiovascular protection. For patients with proteinuria of more than 1 g/day, the target for blood pressure is 125/75 mm Hg.²⁵ Numerous studies have shown that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are cardioprotective and can reduce proteinuria and slow progression of renal disease in both diabetic and nondiabetic chronic nephropathy patients (see Chapter 76). A recent meta-analysis of the largest renal protection trials using ACE inhibitors showed that the degree of protection is closely correlated to the degree of proteinuria reduction. None of these studies has focused on the specific effect of renin-angiotensin system (RAS)

blockade in MN. In secondary analyses, the number with MN has been small, and although the use of ACE inhibitors has been associated with significant improvement in some series, their antiproteinuric effect was modest (<30% reduction in proteinuria) in others.²⁶ When effective, the benefit of RAS blockade occurs early, usually within the first 3 months of initiation of treatment. Even patients at low risk for progression (proteinuria <4 g/24 h) should be treated with ACE inhibitors or ARBs because this may reduce proteinuria and offer additional renal protection with little chance of significant adverse effect. Patients must also follow a low-salt diet to achieve the maximum benefit from RAS blockade.

Proteinuria is also an independent risk factor for cardiovascular morbidity and mortality. When the proteinuria is in the nephrotic range, there is a clear increase in cardiovascular risk, with a threefold to fivefold increase in both coronary events and death rates in this population.²⁷ Patients with significant proteinuria almost always have elevated serum cholesterol and triglyceride levels. Although it is not proven, we recommend the use of statins to reduce low-density lipoprotein cholesterol to 100 mg/dl (2 mmol/l) or lower (see Chapters 76 and 78).^{28,29}

It is recommended that both RAS blockade and lipid control be initiated early in the MN patients, although reaching a goal of complete remission or even partial remission in patients at higher risk of progression (with persistent proteinuria >5 g/24 h) with conservative treatment alone is unlikely. Dietary protein intake may be restricted to 0.8 g/kg body weight per day of high-quality protein²⁵ with additional dietary protein (gram per gram) to correct for urinary losses. Dietary protein restriction has been associated with reduced proteinuria (15% to 25%) and a slowing in renal disease progression but has never been shown to induce a complete remission or to add to effects obtained with RAS blockade. Protein restriction must be carefully monitored in nephrotic patients to avoid malnutrition.

Patients with severe nephrotic syndrome are at increased risk for thromboembolic complications, and prophylactic anticoagulation has been shown in retrospective reviews to be beneficial in reducing fatal thromboembolic episodes in nephrotic patients with MN without a concomitant increase in the risk of bleeding.³⁰ However, no randomized controlled trial has ever been done. Hence, there is no current consensus about prophylactic anticoagulation (see also Chapter 15) and no laboratory test that can predict with any accuracy such an event in any one patient. Certain clinical scenarios do have a higher likelihood of such an event and thus deserve more careful physician monitoring. These include patients with severe and persistent nephrotic syndrome (proteinuria >10 g/day and serum albumin <2.5 g/day). The majority of practicing nephrologists, however, will still wait until a primary thromboembolic event has occurred before using anticoagulants.

Other agents that have been tried with modest effects in small numbers of patients include probucol,³¹ a lipid peroxidation scavenger, and high-dose intravenous immune globulin, an agent with multiple effects on antibody-mediated tissue injury.³²

Immunosuppressive Therapy

Several regimens using a variety of immunosuppressive agents have been shown to be successful in reducing proteinuria in MN, but many questions remain unresolved: What should be the duration of conservative therapy while awaiting a spontaneous remission? How is it determined when to initiate immunosuppressive therapy? What is the most effective and safest of the

available agents? and How long should treatment be given before futility is assessed?³³

Corticosteroids

There have been three randomized controlled trials (RCTs) of corticosteroids in the treatment of idiopathic MN.^{34,35} The overall consensus has been no significant long-term beneficial effect on proteinuria, rate of disease progression, or renal survival. The use of oral corticosteroids as a single agent for the treatment of MN is therefore not recommended. The one exception may be the Asian population, in which long-term observational studies have indicated improvement in both proteinuria and renal function preservation with use of corticosteroids as monotherapy.³⁶

Cytotoxic Agents Combined with Corticosteroids

In patients at moderate risk of progression, a significant benefit has been described with the combination of a daily oral dose of a cytotoxic agent (either cyclophosphamide or chlorambucil) alternating monthly with corticosteroids (methylprednisolone pulses 3×1 g, intravenously, at months 1, 3, and 5; and oral prednisone, 0.5 mg/kg on alternate days for 6 months)³⁷⁻³⁹; complete or partial remission of the nephrotic syndrome was seen in close to 80% of treated patients, a threefold to fourfold increase compared with the control group. Both progression rate and renal survival were significantly improved. Both treatment regimens were remarkably safe, although relapses were seen within 2 years in 30% of the treatment group. Very similar results were obtained in an RCT ($n = 93$) using this same regimen to treat MN patients of Asian ethnicity.⁴⁰ Because the results of a cyclophosphamide-based regimen were similar to one based on chlorambucil,⁴⁰ cyclophosphamide is most commonly used because of a better safety profile.

The only RCT ($n = 26$) using cytotoxic agents in patients at high risk of progression (mean creatinine, 2.3 to 2.7 mg/day; proteinuria, 11 g/day) noted no statistical differences in proteinuria, remission rate, or rate of decline of renal function between the corticosteroid-alone and the combined treatment group.⁴¹ However, this RCT employed monthly intravenous doses of cyclophosphamide rather than the oral regimen used in the Italian and Indian studies.

In older, smaller studies, these cytotoxic agents, even with appropriate adjustments in dose, have produced variable effects on outcome and significant adverse events in a high percentage of patients.⁴²⁻⁴⁴ The most recent longer term studies in high-risk patients prospectively studied 65 patients with MN and serum creatinine concentration above 1.5 mg/dl treated with oral cyclophosphamide for 12 months and corticosteroids (same scheme as before).^{45,46} Renal survival was 86% after 5 years and 74% after 7 years. Partial remission occurred in 56 patients. The relapse rate was similar to earlier cytotoxic-corticosteroid regimens, 30% at 5 years. Treatment-related complications were significant and occurred in two thirds of patients, mainly bone marrow suppression and infections. The majority of adverse events could be handled by dose reduction, although some required permanent discontinuation of treatment.

A recent meta-analysis showed that the use of alkylating agents was associated with higher remission rates (partial or complete remission), but no statistical benefit of cytotoxic drug therapy was demonstrated compared with placebo in rates of ESRD or death.⁴⁷ The difficulty with this type of analysis is that the endpoint of renal survival is far beyond the termination point of most clinical trials.

In summary, cyclophosphamide used in combination with corticosteroids appears to be effective in the treatment of patients with nephrotic-range proteinuria due to idiopathic MN, especially if renal function is well preserved at the time of initiation of therapy. This combination may work even in those with impaired renal function, but the supporting data are much less compelling, adverse effects are higher, and the likelihood of benefit is reduced, especially in patients with advanced renal failure (GFR <30 ml/min).⁴⁶ The favorable effects are maintained beyond the 1-year treatment period, but relapse rates approach 35% by 2 years. The adverse effects of cyclophosphamide when it is used long term are the major drawbacks to the universal application of this form of therapy. These include increased susceptibility to infections, anemia, thrombocytopenia, nausea, vomiting, sterility, and, in the long-term, malignant disease. Recent evidence suggests that the risk of cancer is accelerated at a much lower level of exposure than previously considered; the standardized incidence ratio was increased in a number of malignant neoplasms with total cyclophosphamide exposure as low as 36 g (approximately equivalent to 100 mg/day for 1 year).⁴⁸

Calcineurin Inhibitors

Early uncontrolled studies using cyclosporine suggested an initial benefit but a high relapse rate. Cyclosporine may reduce proteinuria not only through its immunosuppressive effects but also by direct effects on the podocyte. In a single blind RCT, 51 patients with corticosteroid-resistant MN were treated for 6 months with cyclosporine (2 to 5 mg/kg) plus low-dose prednisone and compared with placebo plus prednisone.⁴⁹ Complete remission and partial remission were seen in 75% of cyclosporine-treated patients versus 22% of the placebo controls. Cyclosporine was well tolerated, and no adverse events requiring discontinuation of treatment were seen. However, relapses were common at 45% within 1 year after discontinuation of treatment. There has been only one RCT using cyclosporine in patients with high-grade proteinuria and progressive renal failure.⁵⁰ A reduction in both proteinuria and rate of loss of renal function was seen with cyclosporine compared with placebo that was sustained for up to 2 years after the drug was discontinued. Treatment with longer term cyclosporine (i.e., 12 months) has resulted in a higher rate of complete remission and partial remission (84%). In addition, persistence of remission was maintained with doses of cyclosporine as low as 1 to 2 mg/kg, although relapses were still common if the cyclosporine level fell below 100 ng/ml. Time to remission with use of cyclosporine varies from a few weeks to several months. This suggests that if no significant reduction in proteinuria ($<40\%$) is noted within 3 to 4 months, a change in therapy may be warranted.

Significant adverse effects seen with this agent include hypertension, gingival hyperplasia, gastrointestinal complaints, muscle cramps, and, most important, nephrotoxicity, which is dose and duration of treatment dependent. Patients at particular risk are those with initial impaired renal function, especially if it is accompanied by extensive intrarenal vascular disease or chronic tubulointerstitial damage on biopsy.

In a recently completed 12-month RCT ($n = 48$), tacrolimus monotherapy was compared with a control group.⁵¹ Proteinuria remission was 76% with tacrolimus versus 35% in the control group, and progression rate was also substantially slowed by the calcineurin inhibitor. The relapse rate after stopping of the drug, however, approached 50% by the end of 2 years of follow-up.

Mycophenolate Mofetil

Studies using mycophenolate mofetil (MMF) in MN have produced conflicting results. However, even in the most optimistic study, although initial response was high (used in combination with prednisone), the relapse rate within months approached 50%. The most pessimistic study (the only RCT), in comparison to conservative management only, showed no difference in remission rates.^{52,53} Follow-up time was limited and the numbers in the latter study were small, but the reason behind the marked differences between these two trials is not obvious. In a small retrospective study in corticosteroid-resistant Asian MN patients, a higher response with MMF was observed, partial remission rate approaching 50%, possibly related to the ethnic characteristics of the population studied. The role of MMF in the treatment of MN is currently uncertain.

Rituximab

In several pilot studies, rituximab, despite substantial variations in the dose and timing of the drug, consistently reduced proteinuria by 60% to 70%.⁵⁴⁻⁵⁶ The relapse rate, however, may be significantly less than with calcineurin inhibitor or cytotoxic-based regimens. The best predictor of which patients will respond to rituximab is unknown, although the absence of interstitial disease on the biopsy specimen may improve response rate. An RCT needs to be done before widespread use of this agent is advocated, given its very high cost and unknown long-term toxicity in this disease.

Ecuzumab

Ecuzumab is a humanized anti-C5 monoclonal antibody designed to prevent the cleavage of C5 into its proinflammatory byproducts. An RCT in 200 patients with MN that compared this agent with placebo during a total of 16 weeks showed no significant effect on proteinuria or renal function, but effective complement inhibition was not achieved.⁵⁷

Adrenocorticotrophic Hormone

Two small studies have reported the use of an intramuscular long-acting synthetic form of adrenocorticotrophic hormone (ACTH) in MN.^{58,59} The exact mechanism of action of this agent in MN is unknown but likely unrelated to corticosteroid effects because corticosteroids alone are not beneficial in MN. A dose escalation study showed prolonged remission in the majority of MN patients when they were treated with ACTH 1 to 2 mg weekly intramuscularly for a year. In a small RCT ($n = 32$), ACTH, with use of a similar dose regimen, was compared with a standard cytotoxic plus corticosteroids regimen. The remission rate was equal in the two groups, between 80% and 90%, but the relapse rate in the ACTH group was lower (14% versus 30%) after a follow-up of 1 year. Side effects of ACTH were few and included fluid retention, sleep disturbances, and bronze discoloration of the skin. Potassium supplementation was required in the majority of patients in one trial.⁵⁸

Treatment Summary

Control of proteinuria, specifically achieving either a complete or partial remission of the nephrotic syndrome, is associated with prolonged renal survival and a slower rate of renal disease progression in MN. Supportive or conservative care should be given in all cases first and should include the use of diuretics, antihypertensive agents such as ACE inhibitors and ARBs (potentially renal protective), and lipid-lowering agents. In

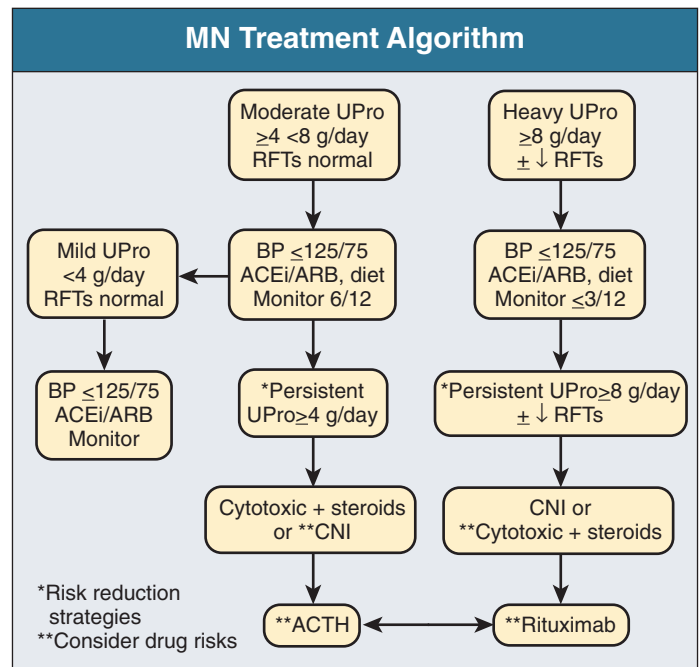

Figure 20.10 Algorithm for the treatment of membranous nephropathy. Details of possible therapies are discussed in the text. ACEi, ACE inhibitor; ACTH, adrenocorticotrophic hormone; ARB, angiotensin receptor blocker; BP, blood pressure; CNI, calcineurin inhibitor; RFT, renal function test; UPro, urinary protein.

patients who require disease-specific therapy, the choice of agents remains controversial. A suggested management algorithm based on the level and persistence of proteinuria is outlined in Figure 20.10.

Both cytotoxic-corticosteroid combinations and calcineurin inhibitors have proved effective in reducing proteinuria in moderate or high-risk MN patients. The physician, in concert with the patient, must take into account all factors related to risk-benefit to arrive at the best decision about which of these therapies should be used first. These approaches are not mutually exclusive and can be used in sequence if the first one chosen does not succeed in inducing a remission or adverse effects are untenable. Ideally, one should leave 2 to 3 months between treatment regimens to help immune system recovery. Alternatively, a second course of the same immunosuppressive regimen could be used, but at the potential cost of cumulative toxicity, or a switch to another treatment regimen may be indicated if the patient's risk profile has changed. Preliminary evidence on the use of rituximab or long-acting ACTH suggests that both may be effective, and safer, than our current regimens, but both need to be assessed further before being widely recommended. Patients with severe renal impairment (GFR <30 ml/min) are less likely to benefit from immunosuppressive therapy, and the risks of treatment may favor conservative therapy as the best option for these patients.

Membranoproliferative Glomerulonephritis, Dense Deposit Disease, and Cryoglobulinemic Glomerulonephritis

F. Paolo Schena, Charles E. Alpers

DEFINITION

Membranoproliferative glomerulonephritis (MPGN), or mesangiocapillary glomerulonephritis (GN), is characterized by diffuse proliferative lesions and widening of the capillary loops, often with a double-contoured appearance. MPGN may be idiopathic or secondary to chronic infections, cryoglobulinemia, or systemic autoimmune disorders that result in aberrant immune complex formation. Three types of MPGN have been described. Type I is characterized by immune deposits in the subendothelial space (capillary wall thickening) and in the mesangium. Type II, also known as dense deposit disease (DDD), is defined by dense deposits within the mesangium and in the basement membranes of the glomeruli, tubules, and Bowman's capsules. On the basis of its unique ultrastructural appearance and the varied morphologic patterns of injury, DDD is best considered a disease entity separate from MPGN. We include DDD in this chapter because of the extensive literature that identifies it as MPGN type II. Type III is a variant of type I, characterized by extensive subendothelial and subepithelial electron-dense deposits. This process is accompanied by alterations and remodeling of the lamina densa of the glomerular basement membrane (GBM) and newly elaborated lamina densa-like material.

ETIOLOGY AND PATHOGENESIS

Although it is frequently idiopathic, the histologic diagnosis of MPGN should provoke a search for secondary causes (Fig. 21.1).¹ In children and young adults (<30 years) with DDD (MPGN type II), the disease is often associated with the presence of nephritic factors, which are IgG or IgM autoantibodies that bind to and stabilize the C3 convertase of the alternative (C3bBb) or classical (C4b2b) pathway (Fig. 21.2), thus resulting in continued complement activation with a depletion of various complement components. In older adults (>30 years), MPGN type I is frequently associated with cryoglobulinemia and hepatitis C virus (HCV) infection.

MPGN type I is most likely to occur in the setting of chronic immune complex diseases, for example, when the host cannot eliminate a foreign antigen effectively despite a humoral response. This may account for the MPGN observed with chronic blood-borne viral (hepatitis C and hepatitis B), bacterial (endocarditis, infected ventriculoatrial shunt), and malarial infections (see Chapter 55). A histologic pattern resembling MPGN can also be observed in chronic immune complex diseases associated with autoimmune diseases such as lupus. Chronic immune complex disease and MPGN may also occur if the host has a defect in clearing immune complexes, as in complement deficiency, or

when the reticuloendothelial system is impaired, as occurs with liver or splenic disease. Hereditary deficiencies of the classical pathway of complement (C1q, C2, C4) and of C3 are associated with the development of MPGN in addition to predisposing to lupus and bacterial infections. MPGN type I also is associated with some malignant neoplasms (especially chronic lymphocytic leukemia and lymphoma).

MPGN type I results from the glomerular deposition of immune complexes from the circulation or from circulating antigens and immunoglobulins that deposit in the glomerulus to form immune complexes *in situ*. These complexes preferentially localize in the mesangium and subendothelial space of the capillary walls. Once localized, the immune complexes typically activate complement through the classical pathway, leading to the generation of chemotactic factors (C5a), opsonins (C3b), and the membrane attack complex (C5b-9) as well as low C3 and C4 serum levels. In some patients, complement is activated by the C4 nephritic factor; in other cases, activation of complement may occur by the mannose-binding lectin pathway (see Fig. 21.2). Mannose-binding lectin, a lectin that binds IgG and activates complement, has been localized to the immune deposits of some patients with MPGN type I.² Complement activation results in the release of chemotactic factors that promote platelet and leukocyte accumulation (Fig. 21.3; see also Fig. 21.2). Leukocytes release oxidants and proteases, mediating capillary wall damage and proteinuria and a fall in the glomerular filtration rate. Cytokines and growth factors released by both exogenous and endogenous glomerular cells lead to mesangial proliferation and matrix expansion.

The pathogenesis of DDD is intricately linked to continual overactivation of the alternative pathway of complement (see Fig. 21.2). This can occur in humans through a dysfunctional constitutive inhibitor of alternative pathway activation (e.g., of factor H, see later discussion), such that there is unregulated and sustained activity of C3, or through the presence of an IgG or IgM autoantibody (C3 nephritic factor [C3Nef]) that binds the alternative pathway C3 convertase (C3bBb) and prevents its inactivation by factor H (see Fig. 21.2). The consequence is a low C3 level but normal circulating levels of C2 and C4 and terminal (C5 through C9) complement pathway components. The most commonly encountered defect in DDD is the C3Nef interaction with C3 convertase. C3Nef, although it is highly associated with DDD, is not specific for DDD and may also be encountered in some patients with MPGN type I and even in some healthy individuals.³ The presence or absence of C3Nef therefore does not have clinical prognostic significance and does not independently predict recurrence of disease in allograft kidneys.⁴⁻⁶ Likewise, C3 levels in serum also have no significant prognostic importance.

Etiology of Membranoproliferative Glomerulonephritis and Dense Deposit Disease	
Type	Secondary Causes
MPGN Type I	
With mixed (type II or III) cryoglobulinemia	Hepatitis C virus (70%–90% of patients) Other infections: bacterial endocarditis, chronic hepatitis B viral infection Collagen vascular disease: systemic lupus erythematosus, Sjögren's syndrome Malignancy: chronic lymphocytic leukemia, non-Hodgkin's lymphoma
Without cryoglobulinemia	Bacterial infections: endocarditis, abscess, infected ventriculoatrial shunt Viral infections: hepatitis B, C, and G; human immunodeficiency virus; hantavirus Malarial (<i>Plasmodium malariae</i>) Collagen vascular disease (systemic lupus erythematosus–hypocomplementemic urticarial vasculitis) Hereditary complement deficiency (C1q, C2, C4, or C3) Acquired complement deficiency (presence of C4 nephritic factor) Chronic liver disease (especially associated with hepatitis B or C infection, chronic schistosomal infection, with splenorenal shunt for liver fibrosis, and with α_1 -antitrypsin deficiency) Sickle cell disease Malignancy: chronic lymphocytic leukemia, lymphoma, thymoma, renal cell carcinoma
Dense Deposit Disease (MPGN Type II)	
Associated with C3 nephritic factor (C3 Nef)	With or without partial lipodystrophy and retinal abnormalities
Associated with factor H defect	Inherited mutations of factor H (deficiency) Autoantibodies to factor H
MPGN Type III	
Secondary causes similar to MPGN type I (hepatitis C or B, and others)	

Figure 21.1 Etiology of membranoproliferative glomerulonephritis and dense deposit disease.

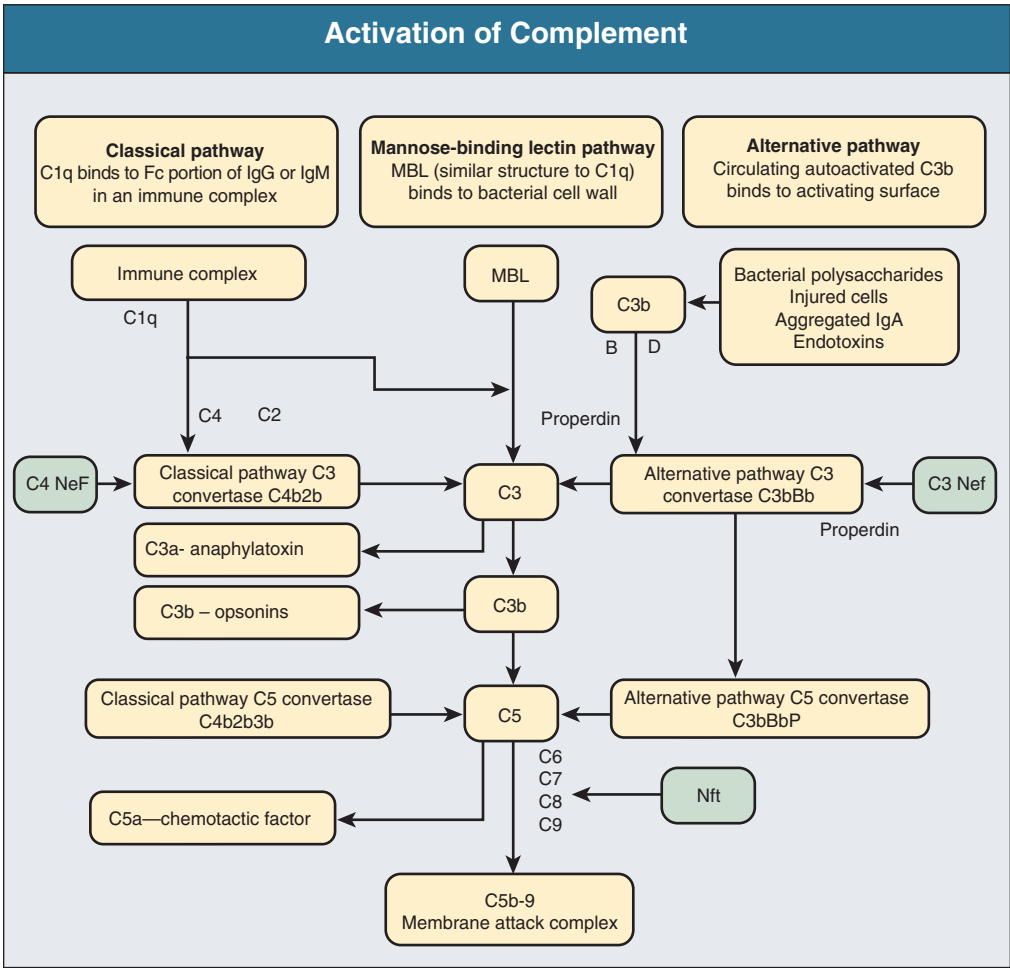

Figure 21.2 Mechanisms of activation of complement pathways including nephritic factors. See text for details. *NeF*, nephritic factor; *Nft*, nephritic factor of the terminal pathway.

Most patients with acquired partial lipodystrophy, an abnormality associated with DDD, also have circulating C3Nef and low serum C3 levels. The lipodystrophy results from complement-dependent loss of the adipocyte, mediated by activation of complement on the adipocyte surface due to both the presence of C3Nef and the overproduction by the adipocyte of adipsin, a protein that is identical to factor D of the alternative pathway (see Fig. 21.2).

Mutations in regulatory proteins of the alternative pathway also can lead to overactivity of C3 and DDD. Genetic mutations in factor H, a cofactor that normally inhibits continued activation of C3 convertase, have been found in patients with DDD and in a spontaneous porcine model of this disease. Factor H-deficient mice also develop GN with some features of DDD, which can be blocked by creation of additional mutations in components of the alternative pathway (e.g., factor B) that prevent further downstream activation of this pathway.⁷ Although most patients with DDD do not have factor H gene mutations, genetic population studies show an association of DDD with individuals having several alleles of both complement factor H gene and the complement factor H-related 5 gene. One of these is the tyrosine-402-histidine (Y402H) polymorphism, which is present in both DDD and age-related macular degeneration, a condition characterized in part by ocular drusen bodies, which are also found in many patients with DDD (see Fig. 21.6B).⁸⁻¹⁰

The pathogenesis of MPGN type III is similar to that of MPGN type I, except that certain characteristics of the immune complexes may favor localization in the subepithelial space. MPGN type III patients exhibit depressed levels of properdin, C3, C5, and one or more of the other four terminal components and elevated levels of C5b-9. This rare disease was mapped to chromosome 1q31-32 in an Irish family.¹¹

Cryoglobulins are immunoglobulins that precipitate in the cold. They are categorized as types I through III (Fig. 21.4). The mixed cryoglobulinemias (types II and III) are most commonly associated with MPGN; these have been strongly associated with chronic HCV infection in up to 80% to 90% of the patients with cryoglobulinemic vasculitis.¹² The non-HCV cases have been associated with other infections (chronic hepatitis B, bacterial endocarditis), collagen-vascular diseases (systemic lupus), and other immunologic disorders (notably poststreptococcal GN). Chronic lymphocytic leukemia may also be associated with cryoglobulinemia and MPGN; interestingly, some of these patients are also infected with HCV and have a circulating monoclonal IgM-κ. Chronic lymphocytic leukemia and lymphoma also have been associated with MPGN in the absence of cryoglobulinemia.¹³

How chronic HCV infection causes cryoglobulinemia is not entirely known. Most patients with HCV infection and

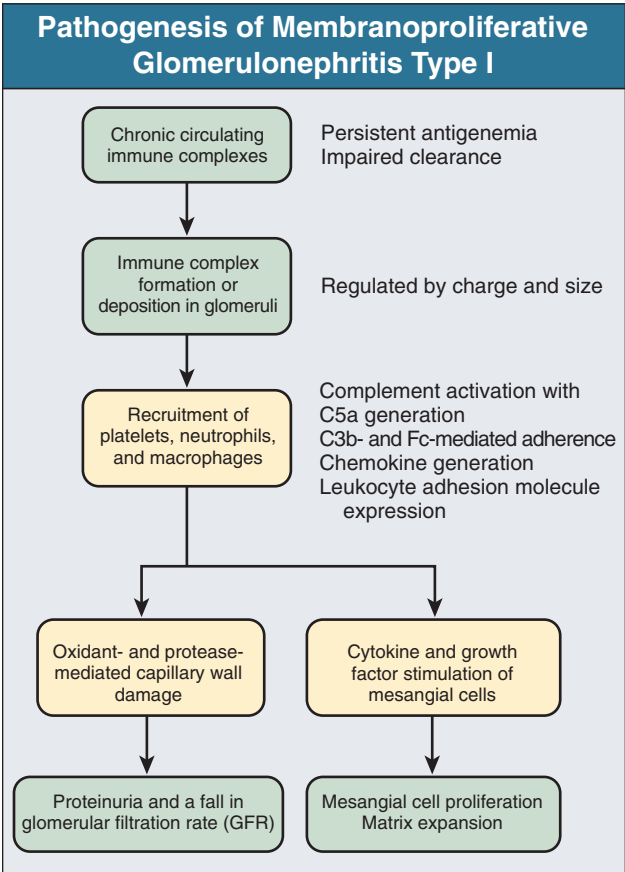

Figure 21.3 Pathogenesis of membranoproliferative glomerulonephritis type I.

Classification of Cryoglobulins		
Type	Composition	Associated Disease
I	Monoclonal IgG, IgA, or IgM	Multiple myeloma (IgG, IgM) Chronic lymphocytic leukemia Waldenström's macroglobulinemia (IgM) Idiopathic monoclonal gammopathy Lymphoproliferative disorders
II	Polyclonal IgG and monoclonal IgM (with rheumatoid factor activity)	Hepatitis C virus Neoplasms: chronic lymphocytic leukemia, diffuse lymphoma, B lymphocytic neoplasia Essential
III	Polyclonal IgG and polyclonal IgM	Infections: viral (hepatitis B and C, Epstein-Barr virus, cytomegalovirus), bacterial (endocarditis, leprosy, poststreptococcal glomerulonephritis), parasitic (schistosomiasis, toxoplasmosis, malaria) Autoimmune disorders: systemic lupus erythematosus, rheumatoid arthritis Lymphoproliferative disorders Chronic liver disease Essential

cryoglobulinemia have an IgM- κ monoclonal antibody with rheumatoid factor activity. This rheumatoid factor can be found with anti-HCV IgG and HCV RNA in the cryoprecipitates. It has been postulated that the IgM is produced by dysregulated B cells infected with HCV. Cryoglobulinemia does not develop until many years (often >10 years) after HCV infection; but by the time chronic active hepatitis or cirrhosis develops, as many as 30% to 40% of patients will have circulating cryoglobulins or other evidence of cryoglobulinemia if it is searched for.¹⁴ Most of these patients will not develop renal disease, but in some patients, possibly those in whom the cryoglobulins have an affinity for fibronectin, the cryoglobulins containing HCV antigens will deposit in glomeruli (Fig. 21.5).¹⁵

Specific HCV-related proteins have been detected in glomeruli, tubulointerstitium, and vessels in patients with cryoglobulinemic HCV-positive MPGN,¹⁶ although difficulties with the antisera available to detect HCV render such findings controversial. In these studies, glomerular HCV deposits have displayed two different patterns: (1) a linear homogeneous deposition along glomerular capillary walls, including endothelial and sub-endothelial spaces; and (2) a granular appearance with distinct deposits in mesangial and paramesangial areas. IgG, IgM, and C3 deposits display features comparable to those of HCV RNA and core protein deposits, suggesting that in cryoglobulinemic HCV-positive MPGN, deposits consist of HCV containing immune complexes that may directly contribute to renal damage.¹⁷ Further pathogenetic insight will likely be provided by new mouse models, including the transgenic thymic stromal lymphopoietin (TSLP) mouse, which develops mixed cryoglobulinemia and MPGN type I, and a DDD model, the factor H-deficient mouse.¹⁸

EPIDEMIOLOGY

In North America and Europe, MPGN (types I and III) and DDD constitute less than 5% of all primary glomerulonephritides. MPGN accounts for 5% to 10% of primary renal causes of nephrotic syndrome in children and adults.¹⁹ It occurs equally in

males and females and in the United States is relatively more common in Caucasians than in African Americans. MPGN presenting in childhood (primarily between the ages of 8 and 14 years) includes types I and III MPGN and DDD and is frequently idiopathic or associated with nephritic factors. By contrast, MPGN presenting in adults (typically older than 18 years) is usually type I or type III and is commonly associated with cryoglobulinemia and HCV infection (see Chapter 55).

The prevalence of MPGN type I is decreasing in Europe, presumably because some chronic infections are becoming less common. On the contrary, in the Middle East (Saudi Arabia), South America (Peru), and Africa (Nigeria), MPGN type I is still quite common because of its association with chronic bacterial, viral, and parasitic infections. The disease may be familial in rare cases, and different histologic lesions may occur in family members (i.e., type I in one member and type III in another).

DDD accounts for less than 20% of cases of MPGN in children and a very low percentage of cases in adults. It is estimated to affect two to three people per million.²⁰

CLINICAL MANIFESTATIONS

MPGN and DDD may present as microscopic hematuria and non-nephrotic proteinuria (35%), as nephrotic syndrome with minimally depressed renal function (35%), as a chronically progressive GN (20%), or with rapidly deteriorating renal function with proteinuria and red cell casts (10%). Systemic hypertension is present in 50% to 80% of patients, and it may occasionally be so severe that the presentation may be confused with that of malignant hypertension.

Pediatric Population

MPGN type I in children and young adults is usually idiopathic and presents as a primary kidney disease without systemic manifestations. Asymptomatic Japanese children diagnosed as a consequence of a urinalysis screening program at school had lower blood pressure, proteinuria, and serum creatinine concentration compared with subjects who were diagnosed after presenting with symptoms.²¹ Thus, early identification of the disease by urinary screening may allow early treatment.

DDD affects females slightly more frequently than males (3:2). It is usually diagnosed in children who are between 5 and 15 years old. Patients present with hematuria, proteinuria, hematuria plus proteinuria, acute nephritic syndrome, or nephrotic syndrome.⁶

Adult Population

MPGN in adults is also often limited to the kidney; but in patients with DDD, partial lipodystrophy that preferentially involves the face and upper body may be present (Fig. 21.6A). It may precede the renal disease by many years. Some patients with DDD will also have mild visual field and color defects and prolonged dark adaptation with mottled retinal pigmentation (drusen bodies; see Fig. 21.6B) and sometimes deterioration of vision. Eye examinations, including dark adaptation, electroretinography, and electro-oculography, should be performed on first presentation and annually thereafter. Indocyanine green angiography of the retina may reveal dense deposits in the ciliary epithelial basement membrane (abnormal fluorescent dots) and choroidal neovascularization.^{22,23}

When MPGN is associated with systemic cryoglobulinemia, patients usually have chronic HCV infection and present with the

Figure 21.6 Dense deposit disease (MPGN type II). **A**, Partial lipodystrophy; note the absence of subcutaneous fat from the face. **B**, Drusen bodies in the retina. (Courtesy Dr. C. D. Short, Manchester, UK.)

triad of weakness, arthralgias, and purpura. The arthralgias are only rarely accompanied by arthritis, are usually symmetric, and classically involve the knees, hips, and shoulders. The purpura (Fig. 21.7) is usually painless, palpable, and nonpruritic; it occurs in “crops” that last 4 to 10 days and preferentially localizes to the extremities. Other manifestations may include ulcerative, vasculitic lesions that classically involve the lower extremities (see Fig. 21.7) and buttocks (Fig. 21.8), Raynaud’s phenomenon, digital necrosis (Fig. 21.9), peripheral neuropathy, hepatomegaly, and, rarely, signs of cirrhosis (clubbing, spider angiomas, ascites). Although most patients with cryoglobulinemia have a chronic waxing and waning course, occasional patients may have a more fulminant presentation, with congestive heart failure (from an HCV-induced cardiomyopathy), infiltrates in the lung from deposition of cryoglobulins (Fig. 21.10), pulmonary hypertension, severe systemic hypertension, or mesenteric ischemia.

In view of the conditions associated with MPGN (see Fig. 21.1), signs of bacterial infection, viral infection, systemic lupus, malignant disease, and chronic liver disease should be sought.

Figure 21.7 Purpura in a patient with hepatitis C virus–associated cryoglobulinemia. Raised purpuric lesions are present on the legs of this individual. The differential diagnosis of purpura and renal disease includes cryoglobulinemia, Henoch-Schönlein purpura, vasculitis, and endocarditis.

Figure 21.8 Purpura in a patient with hepatitis C virus–associated cryoglobulinemia. Purpuric lesions are present on the buttocks and thigh of the patient. Interestingly, note the purpuric lesions along the superior and inferior elastic border of the undergarment line.

Laboratory Findings

MPGN is often associated with depressed complement levels (C3 and total hemolytic complement [CH50]). In MPGN type I and in cryoglobulinemic MPGN, the classical pathway is often activated (low C3, low C4, and low CH50); in DDD, the

Figure 21.9 Necrosis of the distal portion of the little finger in a young woman with essential mixed cryoglobulinemia.

Figure 21.10 Chest radiograph showing nodular infiltrates in the lung secondary to cryoglobulinemic vasculitis in a patient with HCV infection.

alternative pathway is activated (low C3, normal C4, and low CH50); and in type III, C3 is generally low in association with a depression of terminal complement components (C5 through C9). C3Nef activity, strongly but not exclusively associated with DDD, is usually detected in plasma by the hemolytic test or the C3Nef IgG solid-phase assay.²⁴ The presence of rheumatoid factors or cryoglobulins should prompt testing for anti-HCV antibody and HCV RNA. However, MPGN can be associated with HCV infection in the absence of cryoglobulinemia or rheumatoid factors.²⁵ Failure to detect the cryoglobulins may result from improper handling of specimens or may occur because the cryoglobulinemia was transient; however, in some patients (especially in renal transplant recipients), test results for cryoglobulinemia may be persistently negative. Clinical or laboratory evidence of liver disease should prompt a search for causes of chronic liver disease, including hepatitis C, hepatitis B, and, if appropriate, rare entities such as schistosomiasis and α_1 -antitrypsin deficiency.

PATHOLOGY

By light microscopy, MPGN type I is classically described as hypercellular because of both the influx of circulating leukocytes and intrinsic glomerular cell proliferation (typically mesangial cells), leading to a lobular appearance in some cases (Fig. 21.11A).

Accumulation of extracellular material, predominantly matrix, contributes to the frequent mesangial expansion. The glomerular appearance can range from markedly hypercellular to predominantly sclerotic. In its most advanced form, sclerosis can be manifested as nodules indistinguishable from diabetic nodular mesangial sclerosis. Silver stain often shows a double contouring of the GBM ("tram tracks") as a result of the interposition of mesangial cells, leukocytes, or endothelial cells in the capillary wall with the synthesis of new basement membrane material (Fig. 21.12). Monocytes and macrophages are commonly present in the glomerulus and the periglomerular areas.^{1,26}

DDD is characterized by dense deposits within the mesangium and the basement membranes of the glomeruli, tubules, and Bowman's capsules, often visible with eosin and periodic acid-Schiff stains but characteristically identified by electron microscopy. Whereas glomerular changes similar to those of MPGN type I were the most common histopathologic findings in a study in DDD,²⁷ another study identified a mesangial proliferative pattern of injury as most common (45% of patients).²⁸ Other histopathologic patterns identified in this latter series included MPGN (25%), acute proliferative and exudative GN (12%), and crescentic GN (18%); a few could not be readily classified (3%). This histologic heterogeneity of DDD, frequently manifested with a histopathologic pattern other than that of MPGN, and its unique ultrastructural appearance (described later) and unique pathogenesis provide the basis for separation of this entity from its historic classification as a type of MPGN. As in most glomerular diseases, the presence of a significant number of crescents portends a poor prognosis; the prognostic significance of the other glomerular injury patterns is unclear.

The hallmark of MPGN type III is the interruption of lamina densa associated with subendothelial and subepithelial deposits, often confluent, and interspersed with multilayers of new lamina densa. Type I and type III MPGN form a morphologic continuum and thus are not always separable by light microscopy.

Immunofluorescence in MPGN type I and type III frequently shows the deposition of IgM, IgG, and C3 in a granular capillary wall distribution (Fig. 21.11B), although the immunoglobulin deposits may be scant. Staining for C3 in a peripheral (lobular) pattern involving capillary walls and mesangial areas is the most constant and strongest pattern; staining for classical pathway complement components (C1q, C4) may also be seen in MPGN type I. In DDD, C3 but neither classical complement pathway components nor immunoglobulins are detected; this helps distinguish it from other types of injury with an MPGN pattern. The C3 stain is thought to bind to an unidentified substrate at the surface of the dense deposits, which occasionally gives an appearance of tram tracks or mesangial rings.

By electron microscopy, discrete immune deposits can be observed in the subendothelial portions of the capillary walls and mesangial regions in MPGN type I, often in association with platelet and leukocyte infiltration (Fig. 21.11C). The deposits are often discrete but may be confluent in their involvement of the capillary wall. They can be small and sparse or large and numerous such that they are visible by light microscopy. A separation of the endothelium from the GBM can occasionally be observed, usually with some synthesis of new basement membrane material under endothelial cells that have detached from the original basement membrane. Between these layers (old and new) of basement membranes, interposed cells of mesangial, endothelial, or leukocyte origin as well as immune deposits and matrix may be found.

Figure 21.11 Pathology of membranoproliferative glomerulonephritis (MPGN) type I. **A**, Light microscopy shows a hypercellular glomerulus with accentuated lobular architecture and a small cellular crescent (methenamine silver). **B**, Immunofluorescence usually shows discrete, granular staining of the peripheral capillary wall for IgG (seen here) and C3 and occasionally for IgM and earlier complement components (C1q and C4). **C**, By electron microscopy, numerous subendothelial deposits are observed (arrows) between the duplicated basement membrane; these deposits extend into the mesangium (M). C, capillary lumen; E, endothelial cell nucleus.

Figure 21.12 "Tram tracks" in membranoproliferative glomerulonephritis (MPGN) type I. By silver stain, a double contouring of the glomerular basement membrane (GBM) can be observed in MPGN type I, resembling tram tracks.

Figure 21.13 Electron microscopy of dense deposit disease. Dense material replaces sections of the glomerular basement membrane (GBM).

In DDD, electron microscopy shows replacement of large sections of the GBM with an extremely electron-dense band of homogeneous material, the identity of which remains unknown (Fig. 21.13). Involvement of mesangial regions, Bowman's capsules, and tubular basement membranes by the deposits is common.

Perhaps 15% of MPGN cases demonstrate both subendothelial and subepithelial deposits associated with minute disruptions of the lamina densa and newly elaborated lamina densa-like material (MPGN type III). There can be a continuum of subepithelial deposits in MPGN type I and type III from none or scanty to numerous, making it difficult to separate all cases into type I (scanty or no subepithelial deposits) or type III (numerous deposits) categories. After a number of years of normocomplementemia, the type III lesions can disappear, but this not inevitable.²⁹

Cryoglobulinemic MPGN may appear histologically identical to MPGN type I. However, the cryoprecipitates can occasionally be observed by light microscopy as intracapillary hyaline-like deposits (Fig. 21.14A), and there is often a more pronounced infiltration of macrophages within capillary lumina. Electron microscopy may also show highly organized microtubular or finely fibrillar structures consisting of the precipitated cryoglobulins (Fig. 21.14B).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

MPGN is diagnosed by renal biopsy in patients presenting with nephrotic or non-nephrotic proteinuria, especially when it is accompanied by microhematuria. By light microscopy, other entities may appear histologically similar, including poststreptococcal GN, the thrombotic microangiopathies, paraproteinemias, and fibrillary GN (Fig. 21.15). Immunofluorescence and electron microscopy are critical for separating these diseases. Systemic lupus usually can be eliminated by serologic testing.

Other useful tests are serum C3, C4, CH50, total hemolytic activity of the alternative complement pathway (APH50), and factor H levels. Low complement levels can also be observed in atheroembolic renal disease (low C3 with eosinophilia), in thrombotic microangiopathy, in chronic liver disease (because of decreased synthesis), and in several glomerular diseases including systemic lupus (low C3 and C4) and poststreptococcal GN (low C3). The detection of C3NeF activity in plasma suggests DDD, but C3NeF can also be identified in a significant proportion of patients with MPGN type I and even in healthy individuals. In cases of otherwise idiopathic DDD, screening for mutations of factor H gene is recommended.

Once MPGN is diagnosed, careful evaluation for secondary causes should be conducted (see Fig. 21.1 and Chapter 55).

Figure 21.14 Pathology of cryoglobulinemic membranoproliferative glomerulonephritis (MPGN). **A**, Although cryoglobulinemic MPGN may histologically appear similar to MPGN type I (see Fig. 21.11), discrete precipitates of cryoglobulins may occasionally be found occluding individual capillary loops. **B**, In addition, electron microscopy shows organized fibrillar or tubular structures consistent with cryoglobulins (arrows). (**A** reprinted with permission from reference 30. **B** reprinted with permission from reference 31.)

NATURAL HISTORY

Idiopathic MPGN in childhood has a relatively poor prognosis, with 40% to 50% of untreated patients progressing to renal failure during 10 years. Idiopathic MPGN in adults also carries an unfavorable prognosis. Five years after biopsy, 50% of patients either die or need renal replacement therapy (dialysis or transplantation). This proportion increases to 64% after 10 years. Risk of progression increases with elevated creatinine, nephrotic proteinuria, and severe hypertension or if a biopsy specimen shows more than 50% crescents or marked interstitial fibrosis.³²

TRANSPLANTATION

The severity of crescent formation in native kidney biopsy specimens has predictive value for recurrence of disease in subsequent renal allografts.³³ For further discussion of recurrent MPGN and DDD, refer to Chapter 104. Systemic activation of the complement system makes recurrence more likely. HCV-associated MPGN can also occur *de novo* or recur in renal transplant recipients and after liver transplantation.

TREATMENT

The initial approach to MPGN aims at identification of the etiology, if possible, and initiation of supportive antiproteinuric and antihypertensive measures (see Chapter 76). Treatment

Diseases that Histologically Resemble Membranoproliferative Glomerulonephritis

Paraproteinemias: especially fibrillary glomerulonephritis, light-chain nephropathy
Thrombotic microangiopathies: hemolytic-uremic syndrome, scleroderma, radiation nephropathy, malignant hypertension
Glomerulosclerosis in liver diseases
Postinfectious glomerulonephritis
“Transplant” glomerulopathy
Rare diseases: collagen III glomerulopathy, C1q nephropathy, lipoprotein nephropathy

Figure 21.15 Diseases that histologically resemble membranoproliferative glomerulonephritis (MPGN).

plans for the various types of MPGN are discussed in the following sections (Fig. 21.16).

Idiopathic Membranoproliferative Glomerulonephritis in Childhood

Some studies that primarily used historical or nonrandomized controls demonstrated a benefit of alternate-day corticosteroids in childhood MPGN, particularly with administration in the first year of presentation. Although these data are not definitive, we recommend an initial corticosteroid treatment in this population. For children with MPGN with moderate proteinuria (<3 g/day) and normal renal function, we administer prednisone (40 mg/m²) on alternate days for 3 months. In patients with nephrotic syndrome or impaired renal function, this dose of corticosteroids is administered for 2 years. In case of reduction of proteinuria or improvement of renal function, prednisone is tapered to a maintenance dose of 20 mg on alternate days for 3 to 10 years.³⁴ Treatment may be associated with a reduction in hematuria (80%), partial or complete reduction of proteinuria (25% to 40%), and better preservation of renal function (80% at 10 years versus 50% in historical controls). The most important side effects are exacerbation of hypertension, growth retardation, weight gain, and obesity. If no benefit is seen after 1 year of treatment, corticosteroids should be withdrawn and supportive therapy only continued. Responses to alternate-day corticosteroids are superior in children with type I MPGN, whereas children with type III MPGN are more likely to have a progressive reduction in renal function, slower reduction of serum C3, more persistent urinary abnormalities, and more frequent relapses.³⁵

In children with DDD, corticosteroids and calcineurin inhibitors lack efficacy. Removal of C3NeF from the serum through plasma exchange improved serum creatinine in only a few cases.³⁶ The utility of immunosuppressive agents such as mycophenolate mofetil (MMF) has not been established. Plasma infusion with the use of fresh frozen plasma or recombinant factor H can be an effective therapy in patients with DDD secondary to pathologic mutations of factor H gene (*CFH*). This therapy replaces deficient factor H with normal factor H, correcting the complement defect.⁶

Idiopathic Membranoproliferative Glomerulonephritis in Adults

For patients with normal renal function and asymptomatic non-nephrotic-range proteinuria, no specific therapy is necessary.

Suggested Management of Membranoproliferative Glomerulonephritis	
Type	Treatment
All types	Supportive therapy following the recommendations discussed in Chapter 76
Idiopathic MPGN in children	Non-nephrotic proteinuria, normal renal function: follow with 3-month visits Normal renal function and moderate proteinuria (>3 g/day): prednisone 40 mg/m ² on alternate days for 3 months Nephrotic or impaired renal function: prednisone 40 mg/m ² on alternate days (80 mg maximum) for 2 years, tapering to 20 mg on alternate days for 3–10 years
Idiopathic MPGN in adults	Non-nephrotic, normal renal function: follow with 3-month visits Nephrotic or impaired renal function: 6-month course of corticosteroid with/without cytotoxic agents (cyclophosphamide) or other drugs used: cyclosporine, tacrolimus, mycophenolate mofetil (MMF) Rapidly progressive renal failure with diffuse crescents: treat as for idiopathic rapidly progressive GN (see Chapter 24) In the presence of chronic renal failure or nephrotic proteinuria: ACE inhibitors
MPGN associated with HCV or cryoglobulinemia	Non-nephrotic, normal renal function: treat with interferon alpha (see Chapter 55) based on severity of liver disease (diagnosed by biopsy) Nephrotic syndrome, reduced renal function, or signs of cryoglobulinemia: pegylated interferon alfa-2b (1 µg/kg weekly) and ribavirin (15 mg/kg/day) for 12 months, followed by a short-term course of low-dose corticosteroids; if relapse occurs, consider high-dose interferon alfa (10 million U daily for 2 weeks, then every other day for 6 more weeks) Rapidly progressive renal failure or severe symptoms of vasculitis (heart failure, pulmonary disease): methylprednisolone 1 g daily for 3 days, followed by oral prednisone 60 mg/daily with slow taper during 2–3 months Cyclophosphamide (2 mg/kg/day with adjustment for renal function) and cryofiltration may be added as adjunctive therapy; when the prednisone is reduced to 20 mg/day and the cyclophosphamide is discontinued, add interferon alfa MPGN in the renal or liver transplant recipient: consider course of oral ribavirin (0.6–1 g/day)

Figure 21.16 Suggested management of membranoproliferative glomerulonephritis (MPGN).

Close follow-up every 3 to 4 months is recommended.³⁴ In patients with nephrotic syndrome and normal or impaired renal function, a 3- to 6-month course of corticosteroids (prednisone 1 mg/kg body weight per day) may be prescribed. If there is considerable reduction of proteinuria, corticosteroids may be continued at the minimal effective dose. If no response is observed within 3 months, corticosteroids should be stopped; treatment with cyclosporine, tacrolimus, or MMF has been recommended.³⁷

Hepatitis B Virus–Associated Membranoproliferative Glomerulonephritis

In hepatitis B virus (HBV)–associated MPGN, treatment with antivirals aimed at eradication of HBV (interferon, lamivudine) is the recommended initial treatment. Immunosuppressive agents are discouraged because they promote further HBV replication and occasional deterioration of hepatic function (see Chapter 55).

Hepatitis C Virus–Associated Membranoproliferative Glomerulonephritis and Cryoglobulinemia

Treatment options in mixed cryoglobulinemia with renal involvement include corticosteroids, cytotoxic drugs such as cyclophosphamide, and parenteral administration of interferon alfa alone or in association with ribavirin. Parenteral interferon alfa often improves extrarenal manifestations in close association with reduced levels of viremia, but relapse is common after cessation of therapy. As also discussed in Chapter 55, the current treatment of choice in patients with HCV-associated MPGN or cryoglobulinemic MPGN with moderate proteinuria and nonrapid but progressive renal failure is standard interferon alfa (3 MU three times per week) or pegylated interferon alfa (1.5 µg/kg per

week) and ribavirin, adapting the dose to the creatinine clearance or to a trough plasma concentration of 10 to 15 mmol/l. The anti-HCV therapy should be prolonged for 12 months.^{38–41}

High-dose interferon alfa may cause severe influenza-like symptoms, depression or psychosis, the development of hypothyroidism, and, rarely, the development of proteinuria (with a minimal change type of lesion). The most frequent serious adverse side effect of ribavirin is hematopoietic toxicity as well as hemolytic anemia and teratogenic effect. Rituximab is a human-mouse chimeric monoclonal antibody that reacts with the CD20 antigen (thereby selectively targeting B cells). It seems to be as efficient as cyclophosphamide in blocking cryoglobulin production, is better tolerated, and does not enhance HCV replication. It should be administered at a dose of 375 mg/m² per week for 4 weeks.^{42,43} Alternatively, oral cyclophosphamide may be used (2 mg/kg per day for 2 to 4 months).⁴¹

In patients with nephrotic-range proteinuria or progressive renal failure, the anti-HCV therapy is the same. Moreover, treatment may include plasma exchange (3 liters of plasma three times per week for 2 or 3 weeks) and methylprednisolone pulses (0.5 to 1 g/day for 3 consecutive days) followed by oral prednisone 60 mg/day with slow tapering during 2 to 3 months.³⁹ Cryofiltration, that is, double-filtration plasmapheresis with a cooling unit, has been introduced as a means to remove cryoglobulins.⁴⁴

Other Types of Membranoproliferative Glomerulonephritis

MPGN associated with other infections may respond to effective treatment of the underlying pathogenic agent. MPGN associated with α_1 -antitrypsin deficiency has been reported to be cured by liver transplantation, which cures the genetic defect. MPGN associated with malignant disease, such as B-cell lymphoma, may respond to effective treatment of the underlying cancer.

IgA Nephropathy and Henoch-Schönlein Nephritis

John Feehally, Jürgen Floege

DEFINITIONS

IgA Nephropathy

IgA nephropathy (IgAN) is a mesangial proliferative glomerulonephritis characterized by diffuse mesangial deposition of IgA. IgAN was first recognized when immunofluorescence techniques were introduced for the study of renal biopsy specimens. It was described in 1968 by a Parisian pathologist, Jean Berger (it has also been called Berger's disease). Although its most common clinical presentation is visible hematuria provoked by mucosal infection, this is neither universal nor necessary for the diagnosis. IgAN is unique among glomerular diseases in being defined by the presence of an immune reactant rather than by any other morphologic feature found on renal biopsy, and the light microscopic changes are variable. IgAN is the most prevalent pattern of glomerular disease seen in most Western and Asian countries where renal biopsy is widely practiced. At one time, the term *benign recurrent hematuria* was also used for IgAN, but it is now known to be an important cause of end-stage renal disease (ESRD). It is likely that IgAN is not a single entity but rather a common response to various injurious mechanisms.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is a small-vessel vasculitis affecting the skin, joints, gut, and kidneys that predominantly affects children. It is defined by tissue deposition of IgA. HSP was described separately by Schönlein in 1837 and Henoch in 1874. Typically, there is clinical involvement in the skin, gut, and kidneys. The nephritis associated with HSP is also characterized by mesangial IgA deposition; indeed, the renal histologic features of Henoch-Schönlein (HS) nephritis are indistinguishable from those of IgAN. HS nephritis is differentiated from IgAN by the extrarenal manifestations.

ETIOLOGY AND PATHOGENESIS

Although infective episodes precede HSP in up to 50% of cases, there is no evidence of a role for any specific antigen. The clinical association of visible hematuria with upper respiratory tract infection in IgAN indicates that the mucosa may be a site of entry for foreign antigens. An infectious source has long been suspected, and there have been occasional reports of IgAN in association with microbial infection, both bacterial (including *Campylobacter*, *Yersinia*, *Mycoplasma*, and *Haemophilus*) and viral (including cytomegalovirus, adenovirus, coxsackievirus, and Epstein-Barr virus). A severe form of IgAN, which may be crescentic, has been reported in association with severe staphylococ-

cal infection. None, however, has been consistently implicated by the finding of microbial antigen in glomerular deposits in typical cases of IgAN. Food antigens have also been proposed (particularly gliadin), but their involvement is not proven. The mesangial IgA may represent a common immune response to a variety of foreign antigens, the original antigen having disappeared from the deposits by the time of the biopsy. Alternatively, it may be an autoimmune disease directed against mesangial antigens, or it may develop through an antigen-independent mechanism such as altered IgA glycosylation.¹

The regular recurrence of IgAN and HS nephritis after renal transplantation (see Chapter 104) strongly implies an abnormality in the host IgA immune system.

IgA Immune System

IgA is the most abundant immunoglobulin in the body and is chiefly concerned with mucosal defense. It has two subclasses, IgA1 and IgA2. Mucosal antigen challenge provokes polymeric IgA (pIgA) production by plasma cells of the mucosa-associated lymphoid tissue; the pIgA is then transported across epithelium into mucosal fluids, where it is released after coupling to secretory component as secretory IgA (sIgA). The function of circulating IgA is less clear; it is bone marrow derived and mostly monomeric IgA1 (mIgA1). Circulating IgA1 is cleared by the liver through hepatocyte asialoglycoprotein receptors and Kupffer cell Fc α receptors.

The mesangial IgA in IgAN is predominantly pIgA1. The clinical association with mucosal infection or superantigens from *Staphylococcus aureus* originally suggested that the mesangial pIgA1 comes from the mucosal immune system. In IgAN, however, pIgA1 production is downregulated in the mucosa and upregulated in the bone marrow. Moreover, the pIgA response to systemic immunization with common antigens is increased, whereas the response to mucosal immunization is impaired. Impaired mucosal IgA responses allowing enhanced antigen challenge to the marrow could be the primary abnormality in IgAN, although this remains unproven. Similarly attractive, yet still unproven, is the hypothesis that some mucosal IgA-producing plasma cells translocate to the bone marrow in IgAN; this could also explain the defective glycosylation of IgA1 in IgAN (see later discussion). Tonsillar pIgA1 production is also increased, although IgAN can occur after tonsillectomy, and the tonsil is a very minor source of IgA production compared with the mucosa or marrow. There are reports of sIgA in the mesangium, but this finding is not easily explained by current pathogenic concepts of IgAN. Hepatic clearance of IgA is reduced, possibly as a consequence of the altered molecular characteristics of IgA in IgAN (see later discussion).

Serum IgA levels are increased in one third of patients with IgAN and HSP. There are elevations in both mIgA and pIgA. High serum IgA *per se* is not, however, sufficient to cause IgAN; high circulating levels of monoclonal IgA (in myeloma) or polyclonal IgA (in acquired immunodeficiency syndrome [AIDS]) only infrequently provoke mesangial IgA deposition.

Circulating macromolecular IgA is characteristic of IgAN. It is often described as IgA immune complexes, although the antigen is only rarely identified. There are circulating IgA rheumatoid factors (IgA against the constant domain of IgG) in 30% of those with IgAN and 55% of those with HSP. Studies *in vitro* indicate that IgA production by mononuclear cells is exaggerated in IgAN and that these cells show abnormal patterns of cytokine production. The direct relevance of these observations to events *in vivo* is uncertain, however.

IgA Glycosylation

IgA1 carries distinctive *O*-linked sugars at its hinge region; IgA2 has no hinge and carries no such sugars. There is good evidence that circulating IgA1 in IgAN and HS nephritis has abnormal *O*-linked hinge-region sugars with reduced galactosylation because of altered IgA production in lymphocytes of patients with IgAN.¹ The pathogenic processes that lead to altered serum IgA1 *O*-glycosylation remain uncertain. There are some data pointing to defective function of the relevant glycosyltransferases

that *O*-glycosylate IgA1, possibly with a genetic basis; other findings suggest that the primary abnormality may be that IgA of mucosal type, which has glycosylation patterns different from serum IgA1, reaches the circulation.²

Mesangial IgA1 in IgAN has the same abnormalities of *O*-glycosylation.^{3,4} The altered glycosylation may lead to IgG anti-IgA autoantibodies and promote mesangial IgA1 deposition by predisposing to the formation of circulating IgA1 immune complexes or by directly modifying IgA1 interactions with matrix proteins and mesangial cell or monocyte Fc receptors.⁵ It may also impair IgA1 clearance by inhibiting IgA1 interactions with hepatic and circulating myeloid cell IgA receptors. Some key elements involved in the pathogenesis of IgAN are summarized in Figure 22.1.

Glomerular Injury After IgA Deposition

Polymeric IgA deposition in the mesangium is typically followed by mesangial proliferative glomerulonephritis (GN). In animal models, codeposition of IgG and complement is necessary for inflammation, but this is not mandatory in human disease. Circulating antimesangial IgG has been associated with disease activity in IgAN; this remains unconfirmed, however. Complement deposits are usually C3 and properdin without C1q and C4. The extent to which IgA engages inflammatory cells in the circulation and especially in the kidney will also determine the

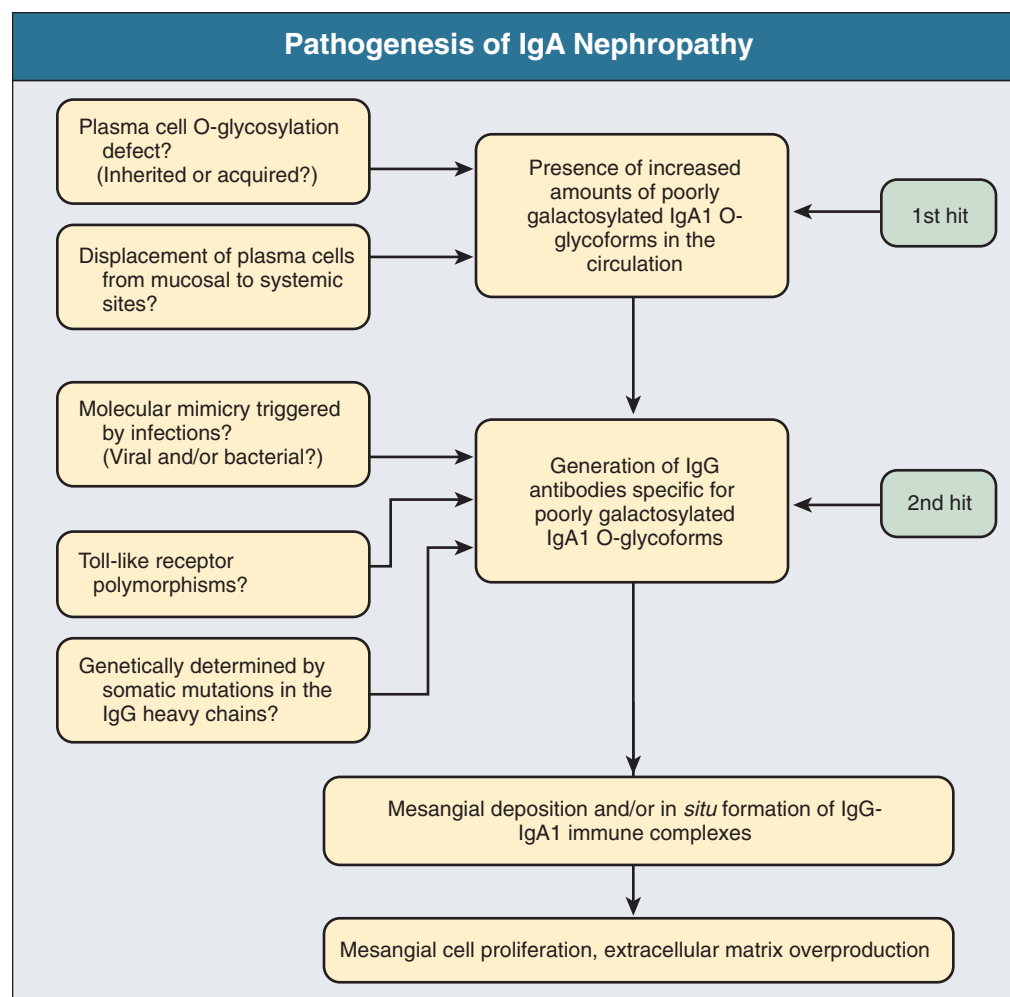

Figure 22.1 Pathogenesis of IgA nephropathy. Proposed mechanisms leading to mesangial deposition of abnormally glycosylated IgA1 and mesangial injury.

intensity of inflammation. Fc receptors for IgA (Fc α receptors) on myeloid and mesangial cells may play a key role.⁶

The mechanisms of mesangial proliferative GN have been studied in detail in animal models, particularly anti-Thy 1 nephritis in the rat. These studies have shown the key role of cytokines and growth factors in mesangial cell proliferation (particularly the B and D isoforms of platelet-derived growth factor⁷ [PDGF]) and in the subsequent matrix production and sclerosis (particularly transforming growth factor β [TGF- β]). Studies of renal biopsy specimens in human IgAN also support a role for PDGF and TGF- β . These mechanisms are not unique to IgAN but are likely to be involved in all forms of mesangial proliferative GN, including those without IgA deposition. Clinical trials based on these pathogenetic insights, in particular with respect to PDGF, are being planned.⁷

Animal Models of IgA Nephropathy

Animal IgA does not have the same characteristics as human IgA1, and some animals also have IgA clearance mechanisms distinct from those in humans. It follows that animal models, even if they provoke mesangial IgA deposits, are not particularly informative about the mechanisms that underlie human mesangial pIgA1 deposition, although they have provided many insights into events after IgA deposits have developed. There is no animal model in existence for HSP.

Relationship Between IgA Nephropathy and Henoch-Schönlein Purpura

Despite some differences in age at onset and natural history of IgAN and HS nephritis,⁸ there is much evidence to support a close pathogenetic link between the two conditions. Monozygotic twins who developed IgAN and HSP, respectively, at the same time have been described. The evolution of IgAN into HSP in the same patient is described in both adults and children, and HSP patients with, end-stage renal disease (ESRD) receiving a renal transplant may experience recurrent disease in the form

of IgAN. Many of the abnormalities of IgA production and handling reported in IgAN are also detected in HSP.

IgA antineutrophil cytoplasmic antibodies (IgA-ANCA) have been proposed as a marker of the systemic features that differentiate HSP from IgAN. Circulating IgA-ANCA has been described in HSP, although findings are not consistent. IgA-ANCA is not found in IgAN.

EPIDEMIOLOGY

IgAN is the most prevalent pattern of glomerular disease in most countries where renal biopsy is widely used as an investigative tool. However, there is striking geographic variation (Fig. 22.2). Genetic variations may be important. For example, in North America, IgAN is less common in African Americans than in Caucasians of European origin. It is also very uncommon among black South Africans. In New Zealand, IgAN is much less common among Polynesians than among Caucasians of European origin, even though Polynesians have an increased prevalence of ESRD due to other renal diseases. Perceived prevalence of IgAN may also be influenced by attitudes to the investigation of microscopic hematuria. A country with an active program of routine urine testing will inevitably identify more individuals with urine abnormalities, but IgAN will be identified only if renal biopsy is performed. Even then, the prevalence of IgAN will be underestimated; a study of kidney donors suggests that the prevalence of IgAN with mesangial proliferative changes and glomerular C3 deposits in the general population in Japan may be 1.6%.⁹

In children, HSP is usually diagnosed on clinical grounds without biopsy confirmation of tissue IgA deposition. Transient urine abnormalities are very common in the acute phase. However, only those with persistent urine abnormalities or with more overt renal disease will come to renal biopsy. Therefore, the incidence of HS nephritis is almost certainly underestimated, with many unidentified mild and transient cases. There is no information on geographic variations in HSP.

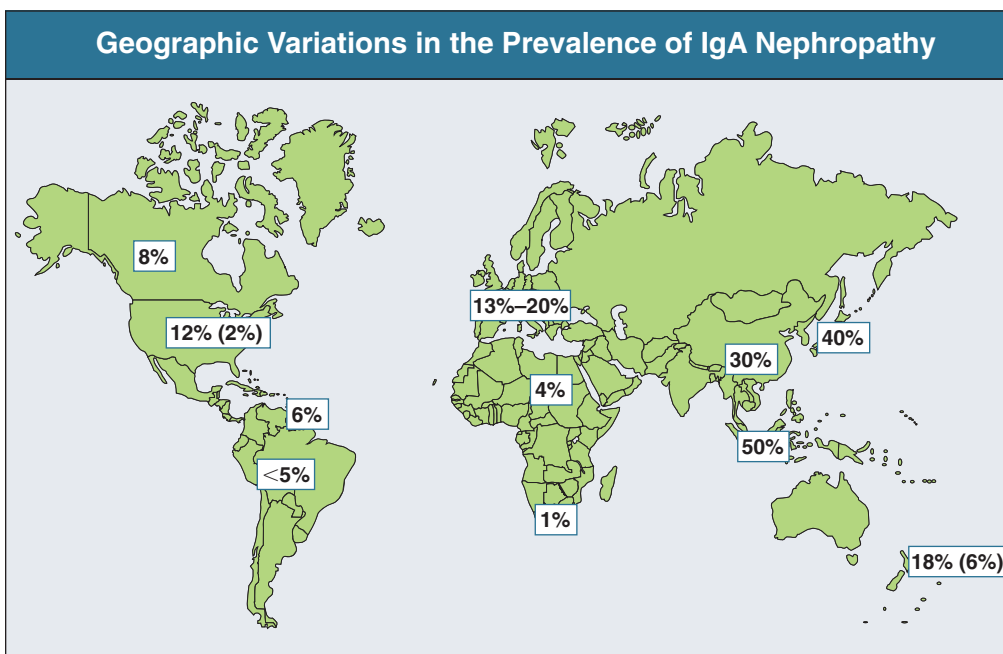

Figure 22.2 Geographic variations in the prevalence of IgA nephropathy.

Percentages of patients with glomerular disease who have IgAN. The figures in parentheses are percentages of glomerular disease in minority racial groups: among African Americans in the United States and among Polynesians in New Zealand.

Genetic Basis of IgA Nephropathy

Urine abnormalities increase in frequency among the relatives of those with IgAN, although only in a few pedigrees is IgAN found in multiple generations. One very large pedigree has been described in Kentucky, and other large families have been found in Italy and Canada. However, more than 90% of all cases of IgAN appear to be sporadic.

In three different kindreds with IgAN, different regions of the genome are implicated in disease susceptibility, emphasizing the polygenic nature of this condition. Investigation of these genome regions has not yet yielded definitive candidate disease susceptibility genes.¹⁰

Many association studies have sought genes associated with disease in sporadic IgAN, so far without consistent findings.¹⁰

CLINICAL MANIFESTATIONS OF IgA NEPHROPATHY

The wide range of clinical presentations of IgAN varies in frequency with age (Fig. 22.3). No clinical pattern is pathognomonic of IgAN. In populations of Caucasian descent, it is more common in males than in females by a ratio of 3:1, whereas the ratio approaches 1:1 in most Asian populations.

Macroscopic Hematuria

In 40% to 50% of cases, the clinical presentation is episodic macroscopic hematuria, most frequently in the second and third decades of life. The urine is usually brown rather than red, and clots are unusual. There may be loin pain due to renal capsular swelling. Hematuria usually follows intercurrent mucosal

infection, commonly in the upper respiratory tract (the term *synpharyngitic hematuria* has been used) or occasionally in the gastrointestinal tract. Hematuria is usually visible within 24 hours of the onset of the symptoms of infection, differentiating it from the 2- to 3-week delay between infection and subsequent hematuria in postinfectious (e.g., poststreptococcal) GN. The macroscopic hematuria resolves spontaneously in the course of a few days. There is persistent microscopic hematuria between attacks. Most patients have only a few episodes of frank hematuria. These become less frequent and resolve during a few years at most. Such episodes are sometimes associated with acute renal impairment.

Asymptomatic Hematuria and Proteinuria

Asymptomatic urine testing identifies 30% to 40% of patients with IgAN in most reported series. Microscopic hematuria with or without proteinuria (usually <2 g/24 h) is noted. The number of patients identified in this way will depend on local attitudes to urine screening as well as on the use of renal biopsy in patients with isolated microscopic hematuria. Most patients with IgAN are asymptomatic and would be identified only when there is population-based urine screening.

Proteinuria and Nephrotic Syndrome

It is rare for proteinuria to occur without microscopic hematuria. Nephrotic syndrome is uncommon, occurring in only 5% of all patients with IgAN. Nephrotic syndrome may occur early in the course of the disease, with minimal glomerular change or with active mesangial proliferative GN. Alternatively, it may occur as a late manifestation of advanced chronic glomerular scarring.

Acute Kidney Injury

Acute kidney injury (AKI) is very uncommon in IgAN (<5% of all cases), although one study reports that it may be the presentation in up to 27% of those older than 65 years.¹¹ It develops by three distinct mechanisms. There may be acute severe immune and inflammatory injury with necrotizing GN and crescent formation (crescentic IgA nephropathy); this may be the first presentation of IgAN, or it may be superimposed on established, less aggressive disease. Rapid deterioration in IgAN in pregnancy may be due to crescentic transformation. Alternatively, acute renal failure can occur with mild glomerular injury when heavy glomerular hematuria leads to tubule occlusion by red cells. Finally, especially in elderly patients, chronic IgAN will predispose to AKI from a variety of incidental renal insults (see Chapter 66).

Chronic Kidney Disease

Some patients already have renal impairment and hypertension when they are first diagnosed. These patients tend to be older, and it is probable that they have long-standing disease that previously remained undiagnosed because the patient neither had frank hematuria nor underwent routine urinalysis. Hypertension is common as in other chronic glomerular disease; accelerated hypertension occurs in 5% of patients.

Clinical Associations with IgA Nephropathy

Although IgAN is clinically restricted to the kidney in most cases, there are case reports of associations with many other

Figure 22.3 Clinical presentations of IgA nephropathy and Henoch-Schönlein purpura in relation to age at diagnosis. HSP is most common in childhood but may occur at any age. Macroscopic hematuria is very uncommon after the age of 40 years. The importance of asymptomatic urine abnormality as the presentation of IgAN will depend on attitudes to routine urine testing and renal biopsy. It is uncertain whether those presenting late with chronic renal impairment have a disease distinct from that of those presenting younger with macroscopic hematuria. Data from patients presenting in Leicester, United Kingdom, 1980 to 1995.

Diseases Reported in Association with IgA Nephropathy			
Disease	Common	Reported	Rare
Rheumatic and autoimmune disease	Ankylosing spondylitis Rheumatoid arthritis Reiter syndrome Uveitis	Behçet's syndrome* Takayasu's arteritis† Myasthenia gravis	Sicca syndrome
Gastrointestinal disease	Celiac disease	Ulcerative colitis	Crohn's disease Whipple's disease
Hepatic disease	Alcoholic liver disease Nonalcoholic cirrhosis Schistosomal liver disease		
Lung disease	Sarcoid		Pulmonary hemosiderosis
Skin disease	Dermatitis herpetiformis		
Malignancy		IgA monoclonal gammopathy	Bronchial carcinoma Renal carcinoma Laryngeal carcinoma Mycosis fungoides Sézary syndrome
Infection	Human immunodeficiency virus, hepatitis B (in endemic areas)	Brucellosis	Leprosy
Miscellaneous		Wiskott-Aldrich syndrome‡	

Figure 22.4 Diseases reported in association with IgA nephropathy: common, reported, and rare. Rare associations have been made in one or two reported cases only. In a disease as common as IgAN, it is therefore uncertain whether they are truly related. *Behçet's syndrome: a systemic vasculitis typified by orogenital ulceration and chronic uveitis. †Takayasu arteritis: a systemic vasculitis involving the aorta and its major branches, most often found in young women. ‡Wiskott-Aldrich syndrome: an X-linked disorder in which increased serum IgA is associated with the triad of recurrent pyogenic infection, eczema, and thrombocytopenia.

conditions, particularly with a number of immune and inflammatory diseases (Fig. 22.4). Their relationship to abnormalities of the IgA immune system is not always clear, and some may represent the coincidental development of unrelated but relatively common conditions.

Mesangial IgA deposition is a frequent finding in autopsy studies in chronic liver disease. Although it is particularly associated with alcoholic cirrhosis, it can occur in other chronic liver disease, including that caused by hepatitis B and schistosomiasis. It is thought to be a consequence of impaired clearance of IgA by the Kupffer cells (which express Fc α receptors) and hepatocytes (which express the asialoglycoprotein receptor). Clinical evidence of renal disease is more common than previously appreciated, and occasionally patients will develop ESRD.

A number of case reports have associated IgAN with human immunodeficiency virus/AIDS. It is not clear whether the polyclonal increase in serum IgA, which is a feature of AIDS, is the predisposing factor.

CLINICAL MANIFESTATIONS OF HENOC-SCHÖNLEIN PURPURA

HSP is most prevalent in the first decade of life but may occur at any age. A palpable purpuric rash, which may be recurrent, occurs on extensor surfaces (Fig. 22.5). There may be polyarthralgia (usually without joint swelling) and abdominal pain caused by gut vasculitis. This may be severe, with bloody diarrhea if intussusception develops. In practice, the diagnosis is made by clinical criteria in the great majority of children, in whom HSP is a self-limited illness. In adults, clinical features

Figure 22.5 Henoch-Schönlein purpura. The rash is a palpable purpuric vasculitis on the lower limbs spreading on extensor surfaces to the buttocks and occasionally to the upper limbs. Histology shows leukocytoclastic vasculitis with IgA deposits in blood vessel walls.

include purpura, arthritis, and gastrointestinal symptoms in 95%, 60%, and 50% of patients, respectively.¹² Renal involvement in adults with HSP is not different from isolated IgAN. Tissue confirmation of IgA deposition by renal or skin biopsy is necessary to establish the diagnosis.

Much renal involvement in HSP is transient. Urine abnormalities are noted during the acute presentation but may disappear. Of those referred to a nephrologist, asymptomatic urine abnormality is still the most frequent clinical manifestation. Nephrotic syndrome occurs in 20% to 30% of patients. AKI may develop as a result of crescentic GN.

PATHOLOGY

The renal histopathologic findings in IgAN and HS nephritis may be indistinguishable (Fig. 22.6).

Immune Deposits

Diffuse mesangial IgA, shown in Figure 22.6B, is the defining hallmark. C3 is codeposited in up to 90% of cases. IgG in 40% and IgM in 40% of cases may also be found in the same distribution. IgA also deposits sometimes along capillary loops (a pattern more common in HS nephritis); in IgAN, this pattern is associated with a worse prognosis. C5b-9 is found with properdin but not C4, indicating alternative complement pathway activation. Disappearance of IgA deposits after prolonged clinical remission has been documented in both children and adults. About one third of the patients also have deposits of sIgA in the mesangium and are characterized by more severe disease.¹³

Light Microscopy

Light microscopic changes are remarkably variable and do not correlate topographically with the IgA deposits. They can be almost normal glomerular architecture, diffuse mesangial proliferative GN (see Fig. 22.6A), focal segmental GN, or, in rare cases, focal segmental necrotizing GN with extracapillary proliferation. Typical cases are characterized by an increase in mesangial cells and mesangial matrix with normal-appearing capillary loops. Focal segmental or global glomerular sclerosis indicates that the disease has been ongoing for some time. In addition to glomerular changes, the preglomerular arterial vessels often exhibit wall hyalinosis and subintimal fibrosis even in cases of only mild arterial hypertension. In long-standing disease, tubulointerstitial inflammation leads to interstitial fibrosis and tubular atrophy in a pattern no different from other progressive glomerular disease. On occasion, IgAN and minimal change nephrotic syndrome coincide (see later under **Nephrotic Syndrome**), in which case light microscopy is normal but there are mesangial IgA deposits.

Morphology is of value in predicting prognosis in slowly progressive cases, although there has been no universal agreement until recently as to the ideal pathologic classification. However, the Oxford classification of IgAN is now being widely accepted.¹⁴

Figure 22.7 Acute kidney injury in IgA nephropathy. Tubular occlusion by red cells. (Hematoxylin-eosin; magnification $\times 300$.) This appearance may be associated with only minor glomerular changes.

Two distinct patterns of injury are seen in AKI. There may be tubular occlusion by red cells with acute tubular epithelial injury in macrohematuria-associated AKI (Fig. 22.7). Alternatively, glomerular injury may be the cause of AKI with necrotizing GN and cellular crescent formation. Such crescentic IgAN may develop on a histologic background of established chronic renal injury due to IgAN or may be the first presentation of IgAN. It is not uncommon to see small numbers of crescents in patients with stable renal function and no other pathologic evidence of severe glomerular inflammation; the term *crescentic IgAN* should not be used for such cases, in which the prognosis is often favorable.

Electron Microscopy

Electron-dense deposits correspond to the mesangial (or capillary loop) IgA, as shown in Figure 22.6C. Typically, electron-dense deposits are confined to mesangial and paramesangial areas, but, in addition, subepithelial and subendothelial deposits can also be seen. Up to one third of patients will have some focal thinning of the glomerular basement membrane (GBM). On occasion, there will be extensive GBM thinning, suggesting a coincident diagnosis of thin membrane nephropathy (see Chapter 46).

Differential Diagnosis of IgA Nephropathy: Conditions Associated with Mesangial IgA Deposition

IgA nephropathy
Henoch-Schönlein nephritis
Lupus nephritis*
Alcoholic liver disease
IgA monoclonal gammopathy
Schistosomal nephropathy

Figure 22.8 Differential diagnosis of IgA nephropathy: conditions associated with mesangial IgA deposition. *Distinguishing lupus nephritis (especially International Society of Nephrology/Renal Pathology Society classes II and III) may cause difficulty. The finding of C1q deposition is useful. It indicates classical pathway involvement found in lupus nephritis but not in IgAN.

DIFFERENTIAL DIAGNOSIS

The diagnosis of IgAN or HS nephritis requires identification of mesangial IgA in the glomeruli. Therefore, it cannot be made without a renal biopsy, no matter how suggestive the clinical presentation may be. Serum IgA is often increased, and there may be IgA in cutaneous blood vessels in IgAN and in both affected and unaffected skin in HSP. Neither finding, however, is reliable enough to support the diagnosis without a renal biopsy. Serum complement components are normal.

Mesangial IgA occurs in other conditions (Fig. 22.8) that can usually be differentiated by clinical, serologic, and histologic criteria. None of the light microscopic features are of themselves diagnostic of IgAN.

Hematuria

Nonglomerular causes of hematuria, particularly stones and neoplasia, must be excluded by appropriate investigations (see Chapter 59). In its most characteristic clinical setting (recurrent macroscopic hematuria coinciding with mucosal infection in a man in the second or third decade of life), the diagnosis can be strongly suspected. Such a diagnosis, however, cannot be made without a biopsy because recurrent macroscopic hematuria also occurs in other glomerular diseases, particularly in children and young adults.

Nephrotic Syndrome

Patients with IgAN occasionally develop nephrotic syndrome, which is indistinguishable from that in minimal change disease (MCD). There is a sudden onset of nephrosis, with biopsy evidence of glomerular epithelial cell foot process effacement and a prompt complete remission of proteinuria in response to corticosteroids. Only hematuria and mesangial IgA deposits persist after treatment. This pattern occurs particularly in children. These patients are usually regarded as having two separate common glomerular diseases, IgAN and MCD.¹⁵

Other patients with IgAN may develop nephrotic syndrome with more structural glomerular damage and lack the response to corticosteroids. The clinical differential diagnosis includes common causes of nephrotic syndrome appropriate for the age of the patient (see Chapter 15).

Chronic Kidney Disease: Hypertension, Proteinuria, Renal Impairment

In this context, IgAN will be clinically indistinguishable from many forms of chronic kidney disease (CKD). The renal biopsy may be diagnostic by identifying mesangial IgA, even when structural damage is so advanced on light microscopy that it has the nonspecific features of ESRD.

Acute Kidney Injury

When AKI occurs in a patient known to have IgAN, renal biopsy should be performed unless there is rapid improvement in renal function after at least 5 days from the onset of kidney function worsening in response to supportive care and vigorous hydration. Renal biopsy may be required to differentiate the tubular occlusion and acute tubular necrosis that occasionally follow heavy glomerular hematuria from crescentic IgAN or other coincidental causes of AKI (see Fig. 22.7).

Differential Diagnosis of Henoch-Schönlein Purpura

In children, the diagnosis of HSP is usually made on the basis of clinical criteria. Confirmatory evidence of tissue IgA deposition will not be obtained unless persistence of renal disease results in a renal biopsy. In adults, the differential diagnosis is much wider and includes other forms of systemic vasculitis, requiring diagnosis by clinical, serologic, and histologic characteristics (see Chapter 24).

NATURAL HISTORY

Natural History of IgA Nephropathy

The overall prognosis of IgAN has now been defined in long-term natural history studies.¹⁶ Although the evidence shows clinical remission (disappearance of hematuria and proteinuria) in up to one third of patients with mild disease, large studies with prolonged follow-up indicate a slow attrition. By 20 years, one fourth of patients will have ESRD, and a further 20% will have progressive impairment of renal function. It is important to appreciate that these natural history data are based on studies initiated more than 20 years ago; however, in a recent study from France, 7-year renal survival in IgAN was still only 82% despite widespread angiotensin-converting enzyme (ACE) inhibitor therapy.¹⁷

Although an active approach to the investigation of microscopic hematuria will increase the size of the cohort of patients found to have IgAN, it will include more with a good prognosis, thus altering the perceived risk of disease progression. Episodes of macroscopic hematuria do not confer a worse prognosis. This may indicate that such episodes occur only early in the natural history of the disease and that patients doing less well from the point of diagnosis in fact were identified at a later stage in their disease. This is also suggested by the adverse influence on outcome of advancing age at diagnosis.

The risk of ESRD is not uniform. As in any chronic glomerular disease, the presence of hypertension, proteinuria, and reduced glomerular filtration rate (GFR) at presentation, as well as histologic evidence of glomerular and interstitial fibrosis, identifies at the time of diagnosis those with a poor prognosis (Fig. 22.9).^{14,16} Hyperuricemia and increased body mass index are also independent risk factors for progression. However, during

Prognostic Markers at Presentation in IgA Nephropathy	
Clinical	Histopathologic
Poor Prognosis	
Hypertension	Mesangial hypercellularity
Renal impairment	Endocapillary proliferation
Severity of proteinuria	Segmental glomerulosclerosis
Hyperuricemia	Tubular atrophy
Gross obesity	Interstitial fibrosis
Duration of preceding symptoms	Capillary loop IgA deposits
Increasing age	Crescents (controversial)
Good Prognosis	
Recurrent macroscopic hematuria	
No Impact on Prognosis	
Gender	Intensity of IgA deposits
Serum IgA level	

Figure 22.9 Prognostic markers at presentation in IgA nephropathy. None of the clinical or histopathologic adverse features, except capillary loop IgA deposits, are specific to IgA nephropathy.

follow-up, only hypertension and proteinuria are reliable predictors of risk of progression.¹⁸ Some evidence suggests geographic variation in risk of progression. A Canadian study indicates that risk of progression is negligible when proteinuria remains below 0.2 g/24 h with normal blood pressure (BP).¹⁸ It also decreases very significantly if proteinuria can be reduced to less than 1 g/day by any therapeutic maneuver.¹⁸ However, in contrast, a study from Hong Kong suggests that among those presenting with isolated microscopic hematuria, although up to 15% lost hematuria during follow-up, as many as 44% may subsequently develop proteinuria, hypertension, or renal impairment during a 7-year follow-up.¹⁹

Pathologic findings and clinical findings together inform prognosis. The Oxford classification of IgAN has shown that mesangial hypercellularity, endocapillary proliferation, and segmental sclerosis, as well as tubular atrophy and interstitial fibrosis, each add prognostic information even when clinical features (proteinuria, hypertension, GFR) are known at presentation and during follow-up.¹⁴

Natural History of Henoch-Schönlein Nephritis

This is less well defined than IgAN. Observations are restricted to those referred for renal biopsy. This therefore excludes the majority of patients with minor transient renal involvement who have an excellent prognosis. The renal prognosis is worse in adults than in children. In adults, up to 40% will have CKD or ESRD 15 years after biopsy. One series reports an increased mortality due to lung and gastrointestinal malignant disease.¹²

TRANSPLANTATION

Recurrent IgA Nephropathy

There is no evidence from transplant registry data that transplant outcome is inferior if IgAN is the primary renal disease (see also Chapter 104). Nevertheless, mesangial IgA deposits

recur in the donor transplant kidney in up to 60% of patients with IgAN.²⁰ They may occur within days or weeks, but the risk increases with the duration of the transplant. The deposits seem benign in the short term and are not often associated initially with light microscopic changes. Graft failure due to recurrent IgAN, associated with proteinuria and hypertension, occurs in about 5% of cases within 5 years but significantly worsens the prognosis of grafts from 10 years onward or in case of repeated transplantation. In pooled series, recurrent IgAN is 30% in living related transplants versus 23% in cadaveric grafts,²¹ but this does not affect graft survival, and living related donation should not be discouraged. However, any urinary abnormality in a potential related donor requires thorough evaluation, including, if necessary, a renal biopsy. Recurrence of crescentic IgAN with rapid graft failure occurs uncommonly and is generally resistant to treatment.

In a few unwitting experiments, cadaver kidneys with IgA deposits have been transplanted into recipients without IgAN. In all cases, the IgA rapidly disappeared, supporting the concept that abnormalities in IgAN lie in the IgA immune system and not in the kidney.

Recurrent Henoch-Schönlein Nephritis

HSP can recur as isolated IgA deposits in the graft (about 50% of transplants), as full-blown yet isolated IgAN, or rarely as a full recurrence of systemic involvement including a rash. The characteristics of renal recurrence are apparently similar to those of recurrent primary IgAN.²⁰ Delay of transplantation once ESRD is reached does not reduce the risk of recurrence.

TREATMENT

Although specific early treatment intervention might influence the IgA immune system abnormalities that underlie IgAN, the mechanisms of chronic disease progression are unlikely to be unique. It is probable, therefore, that studies of such IgAN patients will provide information applicable to many forms of chronic GN for which IgAN is the paradigm.

The balance of risk against benefit for immunosuppressive therapy is often unfavorable in IgAN, except in the unusual circumstance of crescentic IgAN.

The need for randomized controlled trials of adequate power to answer questions about the prevention of ESRD in IgAN is pressing. It is disappointing, despite the prevalence of IgAN and consensus about its definition and natural history, that there are so few such studies.^{21,22} Patients with HSP have been excluded from almost all treatment studies, so it is uncertain whether any strategies developed for IgAN are applicable to HS nephritis.

TREATMENT OF IgA NEPHROPATHY

Treatment recommendations are summarized in Figure 22.10.

Reduction of IgA Production

Tonsillectomy reduces the frequency of episodic hematuria when tonsillitis is the provoking infection. A long-term retrospective study from Japan suggests that tonsillectomy may reduce the risk of renal failure,²³ but this is not supported by studies from Germany and China.²⁴ The lack of controlled trials is particularly important as the natural history is for macroscopic hematuria to become less frequent with time, independent of any

Treatment Recommendations for IgA Nephropathy	
Recurrent macroscopic hematuria (preserved renal function)	Aggressive hydration (no role for antibiotics or tonsillectomy)
Macroscopic hematuria with acute kidney injury	Renal biopsy mandatory if persistent acute kidney injury (see text) Acute tubular necrosis: supportive measures only Crescentic IgAN Induction: Prednisolone 0.5–1 mg/kg/day for up to 8 weeks Cyclophosphamide 2 mg/kg/day for up to 8 weeks (no evidence favoring oral or intravenous route—follow local practice) Maintenance: Prednisolone in reducing dosage Azathioprine 2.5 mg/kg/day
Proteinuria <1 g/24 h (±microscopic hematuria)	No specific treatment
Nephrotic syndrome with minimal change on light microscopy	Prednisolone 0.5–1 mg/kg/day (children 60 mg/m ² /day) for up to 8 weeks, then taper
Non-nephrotic proteinuria >1 g/24 h (±microscopic hematuria)	ACE inhibitor and/or ARB (maximize dosage or combine to achieve target blood pressure and proteinuria <0.5 g/day); for additional measures, see Chapter 76 If proteinuria still >1 g/24 h on maximal supportive therapy and GFR <70 ml/min, consider fish oil—12 g/daily for 6 months. If further progression of renal failure, consider prednisolone (40 mg/day decreasing to 10 mg by 2 years)
Hypertension	ACE inhibitors and ARB are agent of first choice—target blood pressure: 130/80 mm Hg if proteinuria <1 g/24 h; 125/75 mm Hg if proteinuria >1 g/24 h
Transplantation	No special measures required

Figure 22.10 Treatment recommendations for IgA nephropathy. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

specific treatment. Tonsillectomy may be indicated in the occasional patient with recurrent AKI with macroscopic hematuria induced by tonsillitis. There is no role for prophylactic antibiotics. Dietary gluten restriction, used to reduce mucosal antigen challenge, has not been shown to preserve renal function.

Prevention and Removal of IgA Deposits

The ideal treatment of IgAN would remove IgA from the glomerulus and prevent further IgA deposition. This remains a remote prospect while the pathogenesis remains incompletely understood.

Altering Immune and Inflammatory Events That Follow IgA Deposition

Rapidly Progressive Renal Failure Associated with Crescentic IgA Nephropathy

In this uncommon situation, the risk-benefit balance is most strongly placed in favor of intensive immunosuppressive therapy because, untreated, there will be rapid progression to ESRD. Treatment has often combined plasma exchange with prednisolone and cyclophosphamide.²⁵ Early clinical response is favorable, as in other crescentic nephritis. Medium-term results, however, are disappointing; in one half of the reported cases, patients have reached ESRD within 12 months.²⁵ A subset of patients with circulating IgG-ANCA may have a more favorable response to immunosuppressive therapy similar to that seen in other ANCA-positive crescentic nephritis.²⁶ There have been no controlled trials of treatment, so it is not possible to be certain which elements of the regimen (corticosteroids, cyclophosphamide, or plasma exchange) are mandatory.

Early Treatment with Immunosuppressive or Anti-inflammatory Regimens

Corticosteroids Corticosteroids were given in a short-term randomized, controlled trial in nephrotic adults.²⁷ Although the trial overall showed no benefit, there was a small group with very minor histologic changes that responded rapidly to treatment. Nephrotic syndrome may occur in this setting when MCD and IgAN coincide, in which case the nephrotic syndrome will be fully and promptly corticosteroid responsive. A trial of high-dose corticosteroid therapy is therefore justified in IgAN when there is nephrotic syndrome associated with minimal glomerular injury.

Uncontrolled data available for some years have favored the prolonged administration of alternate-day corticosteroids. This approach is further supported by a randomized, controlled trial indicating that 6 months of intravenous pulse methylprednisolone plus alternate-day corticosteroids in adults with low-grade proteinuria protects renal function during long-term follow-up.²⁸

Another controlled trial using smaller doses of corticosteroids in patients with non-nephrotic proteinuria showed some reduction in protein excretion but no protection of renal function.²⁹

It is unfortunate that these trials of corticosteroids were initiated before the importance was appreciated of rigorous BP control and the critical role of renin-angiotensin blockade in proteinuric glomerular disease. Variable achieved BP and inconsistent use of ACE inhibitors and angiotensin receptor blockers (ARBs) left uncertainty about the role of corticosteroids if tight BP control with renin-angiotensin blockade is maintained. However, two studies suggest significant benefits of 6 months of corticosteroids even when BP control and renin-angiotensin

blockade are used in all patients^{30,31}; this evidence is not yet definitive, and further trials are awaited.³²

Cyclophosphamide Cyclophosphamide has been used in combination with warfarin and dipyridamole in two randomized, controlled trials, the results of which are not mutually consistent. Both showed modest reduction in proteinuria, but only one preserved renal function. Cyclophosphamide followed by azathioprine combined with prednisolone preserved renal function in a controlled trial in patients with a poor prognosis.³³ Many physicians regard the toxicity of cyclophosphamide as unacceptable in young adults with IgAN. In another recent study,⁴⁹ adding azathioprine to corticosteroids in proteinuric IgAN patients with a GFR >50 ml/min had no added benefit and only increased side effects.

Mycophenolate Mofetil Mycophenolate mofetil (MMF) has been used in several controlled trials in high-risk patients. Two trials in Caucasian patients failed to demonstrate any benefit, whereas a short-term study in Chinese patients noted reduced proteinuria. Whether racial effects indeed underlie these discrepant results remains to be clarified.³⁴ In another Chinese trial, four of 32 IgAN patients receiving MMF plus corticosteroids died of *Pneumocystis pneumonia*.³⁵

Dipyridamole and Warfarin These have also been given in two controlled trials that showed mutually inconsistent results. There was no benefit in one and preserved renal function in the other.

Cyclosporine Cyclosporine has been used in one controlled trial. There was a reversible decrease in proteinuria. This went in parallel with a decrease in creatinine clearance, suggesting that the changes were a hemodynamic effect of cyclosporine rather than an immune-modulating effect.

Pooled Human Immunoglobulin Pooled human immunoglobulin has given encouraging preliminary results in IgAN with an aggressive clinical course: proteinuria lessened, deterioration of GFR slowed, and histologic activity lessened on repeated renal biopsies.³⁶ No controlled trial is available for this approach.

Treatment of Slowly Progressive IgA Nephropathy

There is little evidence to indicate that the events of progressive glomerular injury are unique to IgAN. Treatments available are nonspecific approaches for chronic glomerular disease (see also Chapter 77), of which IgAN is the most common and most easily defined.

Hypertension

There is compelling evidence of the benefit of lowering BP in the treatment of chronic progressive glomerular disease such as IgAN. In IgAN, there is also evidence that casual clinic BP readings underestimate BP load as judged by ambulatory BP monitoring and echocardiographic evidence of increased left ventricular mass.³⁷ Two prospective, controlled trials strongly support the use of ACE inhibitors in IgAN as first-choice hypotensive agents to minimize proteinuria as well as BP.^{38,39} Low target BPs (<130/80 mm Hg if proteinuria is <1 g/24 h, 125/75 mm Hg if proteinuria is >1 g/24 h) are recommended from a number of large studies of chronic progressive renal disease. In a randomized study of IgAN, achieving a mean BP

of 129/70 mm Hg prevented the decrease in renal function during 3 years seen in those achieving mean BPs of 136/76 mm Hg.⁴⁰

Fish Oil

The favorable effects of supplementing the diet with omega-3 fatty acids in the form of fish oil include reductions in eicosanoid and cytokine production, changes in membrane fluidity and rheology, and reduced platelet aggregability. These features should significantly reduce the adverse influence of many mechanisms thought to affect progression of chronic glomerular disease.

A randomized, controlled trial provides convincing evidence of protection from 2 years of treatment with fish oil in patients with proteinuria and increasing serum creatinine.⁴¹ It is, however, surprising that fish oil did not significantly reduce proteinuria, a major risk factor for progression. Another study showed no advantage for high- over low-dose fish oil.⁴² However, other smaller controlled trials have shown no benefit,⁴³ although severity of renal impairment before treatment was not equivalent in all these studies. Fish oil treatment does not have the drawbacks associated with immunosuppressive treatment. It is safe apart from a decrease in blood coagulability, which is not usually a practical problem, and an unpleasant taste, with flatulence, which may make compliance difficult. Some fish oil preparations contain significant amounts of cholesterol, necessitating close surveillance if such treatment is initiated. A further confirmatory study of fish oil would be of great value.

Recommendation

The treatment of IgAN with proteinuria of more than 1 g/24 h remains controversial. Physicians are increasingly using corticosteroids when there is preserved renal function (GFR >70 ml/min) and fish oil when there is renal impairment (GFR <70 ml/min). Tight control of BP and proteinuria with ACE inhibitors or ARBs should be the first line of treatment, however. Fish oil or corticosteroids should be considered only if proteinuria above 1 g/24 h persists on maximal ACE inhibitor or ARB therapy with BP below 125/75 mm Hg. Azathioprine (or even cyclophosphamide) combined with corticosteroids should be reserved for desperate cases in which all other measures have failed, and this treatment option needs to be well balanced against its associated risks.

Transplant Recurrence

There is no evidence that newer immunosuppressive agents have modified the frequency of recurrent IgA deposits or are of value in recurrent disease. Most clinicians therefore just optimize supportive care in such instances. When crescentic IgAN recurs with rapidly deteriorating graft function, treatment as for primary crescentic IgAN has been used, although evidence of its success is sparse.

TREATMENT OF HENOCH-SCHÖNLEIN NEPHRITIS

Many patients have transient nephritis during the early phase of HSP, which spontaneously remits and requires no treatment. There are no prospective, randomized, controlled trials to guide the treatment of HS nephritis. Most therapeutic studies of IgAN

Treatment Recommendations for Henoch-Schönlein Nephritis

Crescentic nephritis: regimen as for crescentic IgA nephropathy (see Fig. 22.10)
All other Henoch-Schönlein nephritis (including nephrotic syndrome): no specific treatment, supportive measures only
Hypertension: ACE inhibitor and ARB — agents of first choice; target blood pressure: 130/80 mm Hg if proteinuria <1 g/24 h, 125/75 mm Hg if proteinuria >1 g/24 h
Transplantation: cadaveric donor may be preferable to living related donor in children (controversial)

Figure 22.11 Treatment recommendations for Henoch-Schönlein nephritis. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

exclude those with HSP, so it is uncertain whether a number of potential treatments have a role in HS nephritis. Treatment recommendations are summarized in Figure 22.11.

Rapidly Progressive Renal Failure Caused by Crescentic Nephritis

Crescentic nephritis is more common in HS nephritis than in IgAN, particularly early in the course of HSP. There is little specific information on treatment in adults or children, but regimens based on those for other forms of systemic vasculitis are widely used. These have included corticosteroids and cyclophosphamide, with the addition of plasma exchange or pulse methylprednisolone in some cases. There have been no controlled trials, and HS nephritis has usually been excluded from trials of severe nephritis in systemic vasculitis. It is not possible to define the best regimen on available evidence.

Active Henoch-Schönlein Nephritis Without Renal Failure

There is little information about less aggressive HS nephritis. Corticosteroids alone have never been shown to be beneficial. There is no evidence that early use of corticosteroids in HSP may prevent nephritis.⁴⁴ Promising findings with combination therapy of corticosteroids, cyclophosphamide, and antiplatelet agents have been reported in only small nonrandomized studies.⁴⁵ A nonrandomized study reported that prednisolone and azathioprine preserved renal function and improved histologic appearances but relied on historical controls.⁴⁶ There are very few patients with HS nephritis included in the promising studies of immunoglobulin.

Slowly Progressive Renal Failure

Whereas the renal histology and clinical course of slowly progressive HS nephritis and IgAN may be indistinguishable, patients with HS nephritis have not been included in studies of fish oil. Tight BP control with ACE inhibitors or ARBs is recommended for proteinuric HS nephritis as for IgAN.

Transplant Recurrence

No treatment is known to reduce the risk of recurrence. There is some evidence that recurrence is more common and more

likely to lead to graft loss in children receiving kidneys from living rather than deceased donors, although this is not confirmed in adults.^{47,48} If crescentic HS nephritis recurs, intensive immunosuppression may be justified as for primary disease. This, however, has not been thoroughly evaluated.

Antiglomerular Basement Membrane Disease and Goodpasture's Disease

Richard G. Phelps, A. Neil Turner

The syndrome of renal failure and lung hemorrhage was associated with the name of Ernest Goodpasture by Stanton and Tange in their description of nine cases in 1958.^{1,2} All nine patients presented with lung hemorrhage and acute renal failure and died within hours or days. These features had been prominent in the case of a young man who died during the influenza pandemic of 1919, whose postmortem findings were memorably reported by Goodpasture¹: “The lungs gave the impression of having been injected with blood through the bronchi so that all the air spaces were filled” (Fig. 23.1).

Several diseases are now recognized as being associated with alveolar hemorrhage and rapidly progressive glomerulonephritis (RPGN). Nevertheless, this remains a striking clinical entity with relatively few causes and few pathogenetic mechanisms.

Because the first recognized mechanism was anti-glomerular basement membrane (anti-GBM) antibody formation and deposition, Goodpasture's name is firmly associated with anti-GBM disease (Goodpasture's disease), even though this is responsible for only a proportion of patients with Goodpasture's syndrome of lung hemorrhage and RPGN. The terminology used in this chapter is defined in [Figure 23.2](#).

ETIOLOGY AND PATHOGENESIS

Autoimmunity to a Component of the Glomerular Basement Membrane

Goodpasture's disease is caused by autoimmunity to the carboxyl terminal, noncollagenous (NC1) domain of a type IV collagen chain, $\alpha 3(\text{IV})\text{NC1}$, also known as the Goodpasture antigen ([Fig. 23.3](#)).^{3,4} Type IV collagen is an essential constituent of all basement membranes. In most tissues, it is composed of trimers comprising two $\alpha 1$ chains and one $\alpha 2$ chain, but there are also four tissue-specific chains, $\alpha 3$ through $\alpha 6$.^{5,6} Three of these, $\alpha 3$ through $\alpha 5$, are found in GBM as well as in the basement membranes of the alveolus, the cochlea, parts of the eye (including corneal basement membrane and Bruch's membrane), the choroid plexus of the brain, and some endocrine organs.

All patients with RPGN, lung hemorrhage, and anti-GBM antibodies have antibodies to $\alpha 3(\text{IV})\text{NC1}$, usually binding predominantly to a single or a very restricted set of epitopes. Some patients also have antibodies to other basement membrane constituents, including other collagen IV chains, usually in low titer.

Predisposing Factors

Both environmental and genetic factors appear to be important in etiology. There are strong associations between Goodpasture's disease and HLA class II alleles, including DRB1*1501 and

DR4 alleles, whereas DR1 and DR7 confer strong and dominant protection.⁷

Precipitating Factors

The onset of acute disease has long been linked to various precipitating factors. Theories of pathogenesis include factors that alter antigen processing to generate peptides that are usually destroyed or hidden, and to which tolerance is therefore deficient^{8,8a} and molecular mimicry.⁹ None of these are proved. Reports of temporal and geographic clustering of cases suggest an environmental trigger,¹⁰ but no specific infectious agent has been consistently identified. Hydrocarbon exposure has been linked to disease onset in several striking case reports; but in some cases, such exposure may simply trigger lung hemorrhage in patients who already have the disease. Furthermore, exposures of this kind are very common in the modern world. Similarly, cigarette smoking may precipitate lung hemorrhage in patients who already have circulating autoantibodies, but there is no evidence for a role in causation.

There are several instances in which renal trauma or inflammation ([Fig. 23.4](#)) has preceded the development of the disease. These may alter $\alpha 3(\text{IV})\text{NC1}$ turnover and metabolism qualitatively or quantitatively, providing an opportunity for self tolerance to be broken. Qualitative changes in the basement membrane epitopes presented to T cells could be a result of overloading of the usual or recruitment of alternative processing pathways, such as extracellular processing by proteases released into inflamed glomeruli. The quantity of $\alpha 3(\text{IV})\text{NC1}$ presented to T cells may be greater where there has been damage to the basement membrane, as occurs in systemic small-vessel vasculitis (see Chapter 24); some features suggest that an anti-GBM response may be a secondary phenomenon in some patients with vasculitis.^{11,12} The association with membranous nephropathy is interesting as the thickened GBM in that disease contains increased amounts of the tissue-specific type IV collagen chains, including the Goodpasture antigen. The same could apply to a recently suggested possible association with long-standing type 1 diabetes mellitus.¹³

Mechanisms of Renal Injury

The $\alpha 3(\text{IV})\text{NC1}$ autoantibodies ([Fig. 23.5](#)) are central in the pathogenesis of Goodpasture's disease.^{14,15} Antibodies eluted from the kidneys of patients who had died of Goodpasture's disease rapidly bind to the GBM and cause glomerulonephritis (GN) when they are injected into monkeys.¹⁶ Furthermore, the deposited antibodies are predominantly IgG1 and are complement fixing. Contributions to renal injury mediated by such

antibodies come from complement and from neutrophil and macrophage infiltration. T cells are essential for driving autoantibody production by T cell–dependent B cells, and in experimental renal disease, they are critical in producing glomerular crescents,^{14,17} which are a usual feature of Goodpasture's disease. Some experimental anti-GBM GN is clearly predominantly cell mediated.^{14,17}

Agents that downregulate inflammation by inhibiting interleukin-1 or tumor necrosis factor α or that inhibit recruitment of inflammatory cells by blockade of adhesion molecules or chemoattractants suppress injury in experimental models of anti-GBM disease. There is supportive evidence in humans and in experimental animals that the severity of renal injury may be increased by proinflammatory cytokines or by stimuli likely to elicit them, such as bacteremia.¹⁷ Crescent formation is seen in aggressive inflammatory GN. The mechanism by which it is believed to occur is described in Chapter 16 (see Fig. 16.9).

Lung Hemorrhage

Lung hemorrhage in Goodpasture's disease (but not in small-vessel vasculitis, the other major cause of Goodpasture's syndrome) occurs only if there is an additional insult to the

Figure 23.1 Alveolar hemorrhage in a patient with Goodpasture's disease. Open lung biopsy. (Courtesy Dr. E. Mary Thompson, St Mary's Hospital, London, UK.)

lung, which is usually cigarette smoke. However, infection, fluid overload, toxicity from inhaled vapors or other irritants, and the systemic effects of some cytokines are also possibilities. This is probably because the alveolar capillary endothelial cell provides more of a barrier between circulating immunoglobulin and the underlying basement membrane than the diaphragm-free fenestrations of the glomerular capillary endothelial cell do. In the glomerulus, antibodies have direct access to the GBM because of the fenestrations of glomerular endothelium. Other sites at which the Goodpasture antigen is found are not involved in Goodpasture's disease, except possibly the choroid plexus, where the endothelium is again fenestrated, and more rarely the eye.

EPIDEMIOLOGY

Goodpasture's disease is rare, with a possibly increasing incidence in Caucasian populations approaching 1 case per million per annum.¹³ The incidence in black and South Asian populations appears to be lower. The incidence in other racial groups is uncertain. There is a slight male predominance. Lung hemorrhage is more common in younger patients.

CLINICAL MANIFESTATIONS

Between 50% and 75% of patients present with acute symptoms of lung hemorrhage and are found to be in a state of advanced renal failure. Symptoms are usually confined to the preceding few weeks or months, but very rapid progression (during days) or much slower progression (during many months) may occur. A lack of systemic symptoms, other than those related to anemia, is typical, although it is common for an apparently minor infection to trigger the clinical presentation.

Lung Hemorrhage

Lung hemorrhage may occur with renal disease or in isolation. Presenting symptoms may include cough and hemoptysis, but hemorrhage into alveolar spaces may result in marked iron deficiency anemia and exertional dyspnea, even in the absence of hemoptysis. Depending on the degree and chronicity of lung hemorrhage, examination findings may include pallor, dry inspiratory crackles, signs of consolidation, or respiratory distress. Recent lung hemorrhage (Fig. 23.6) typically is shown on the

Definition of Terms		
Term	Definition	Pathogenesis
Pulmonary renal syndrome	Renal and respiratory failure	Many causes (see Figure 23-10)
Goodpasture's syndrome	RPGN and alveolar hemorrhage	Several causes (see Figure 23-11)
Anti-GBM disease	Disease associated with antibodies specific for (any) components of the GBM	Most important are Goodpasture's syndrome and Alport's syndrome post-transplant anti-GBM disease
Goodpasture's disease	Disease associated with autoantibodies specific for $\alpha 3(\text{IV})\text{NCI}$ May include RPGN, lung hemorrhage, or both	Autoimmunity to $\alpha 3(\text{IV})\text{NCI}$
Alport's syndrome post-transplant anti-GBM disease	Glomerulonephritis associated with anti-GBM antibodies developing after renal transplantation in patients with Alport's syndrome	Immunity to foreign collagen IV chains not expressed in Alport's syndrome patients usually $\alpha 3$ or $\alpha 5(\text{IV})\text{NCI}$

Figure 23.2 Definition of terms. GBM, glomerular basement membrane; RPGN, rapidly progressive glomerulonephritis.

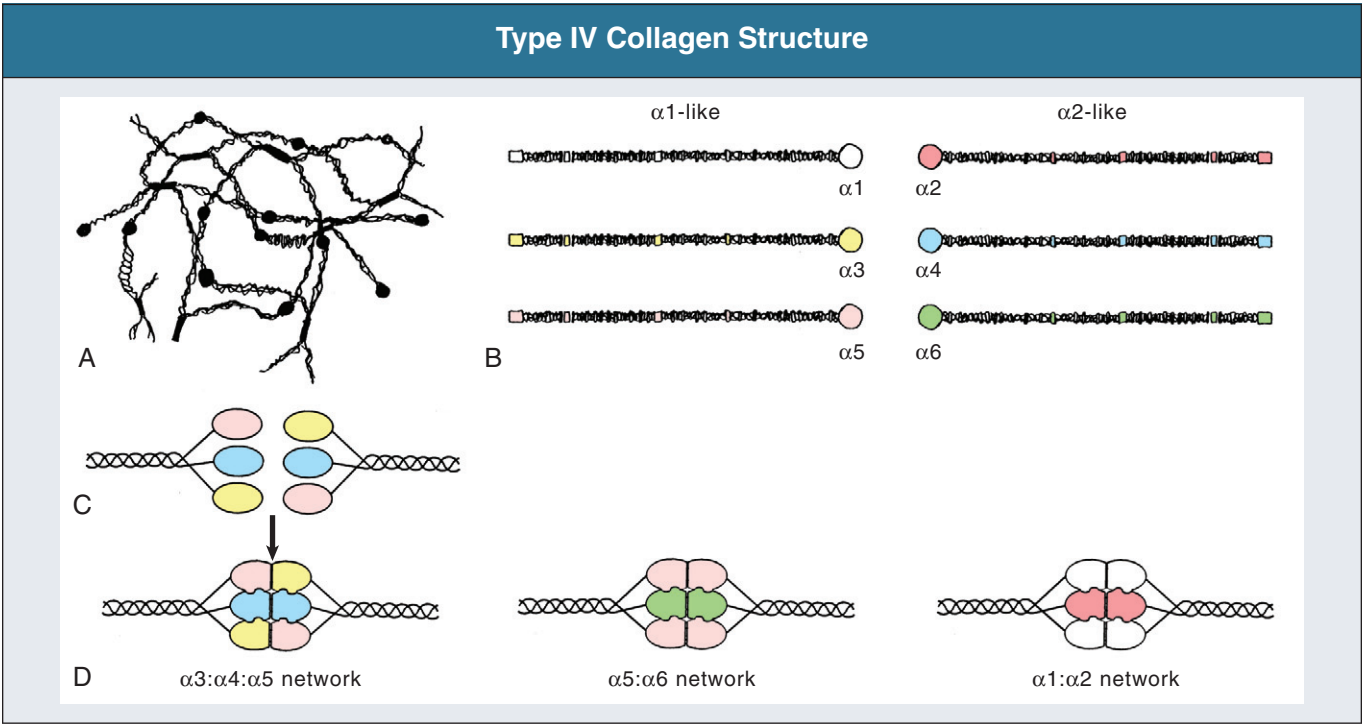

Figure 23.3 Type IV Collagen Structure. **A**, The type IV collagen network makes a “chicken wire” structure in the GBM. **B**, Six paired type IV collagen genes, *COL4A1* to *COL4A6*, encode type IV collagen monomers α1 to α6. These associate in two or three defined monomer types per protomer (carboxyl terminal domains of α3α4α5 shown in **C**, to form three recognized networks shown in **D**, α1α2 is present in almost all basement membranes; α3α4α5 is the major constituent of GBM and is a significant component of alveolar basement membrane and other locations (see text); and α5α6 is found in Bowman’s capsule, skin, esophagus, and other locations.

Predisposing Events Associated with the Presentation of Goodpasture’s Disease
Possibly Induce Autoimmune Response and Disease
Systemic small-vessel vasculitis affecting glomeruli
Membranous nephropathy (MN)
Lithotripsy of renal stones
Urinary obstruction
Precipitate Pulmonary Hemorrhage
Cigarette smoke
Hydrocarbon exposure
Pulmonary infection
Fluid overload

Figure 23.4 Predisposing events associated with the presentation of Goodpasture’s disease.

radiograph as central shadowing that may traverse fissures and give rise to the appearance of an air bronchogram. However, even lung hemorrhage sufficient to reduce the hemoglobin concentration may cause only minor or transient radiographic changes, and these cannot be confidently distinguished radiologically from other causes of alveolar shadowing (notably edema, infection). The most sensitive indicator of recent lung hemorrhage is an increased uptake of inhaled carbon monoxide (DLCO). Patients with lung hemorrhage are usually current cigarette smokers.

Figure 23.5 Autoantibodies to the Goodpasture antigen bound to a normal glomerulus. Shown by direct immunofluorescence in a patient with lung hemorrhage and hematuria. (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)

In isolated lung disease, progressive alveolar or fibrotic disease or pulmonary hemosiderosis may be suspected, although at least hematuria is usually present. This may continue for months or in rare cases recurrently for years before significant renal disease occurs.

Glomerulonephritis

Patients with GN may notice dark or red urine, but progression to oliguria is sometimes so rapid that this phase, if it occurs, is

Figure 23.6 Lung hemorrhage. **A**, Patient with early pulmonary hemorrhage. The chest radiograph still appears normal. **B**, Radiograph taken 4 days later shows the evolution of alveolar shadowing caused by lung hemorrhage.

missed. In one third to one half of patients, GN occurs in the absence of lung hemorrhage. In this subgroup, because systemic symptoms are generally not prominent, presentation is often late with renal failure.

Whatever the early pattern of disease, once significant renal impairment has occurred, further deterioration in renal function is usually rapid. Presentation at the time of or very shortly after acceleration of the disease process is common, and patients may demonstrate very rapid loss of renal function and life-threatening lung hemorrhage. Urinalysis always reveals hematuria (even in apparently isolated pulmonary disease), usually modest proteinuria, and dysmorphic red cells and red cell casts on microscopy. The kidneys are generally of normal size but may be enlarged. Hematuria may be substantial or associated with loin pain in acute disease.

PATHOLOGY

Renal biopsy is essential as it provides diagnostic and prognostic information. Typical appearances are of diffuse proliferative GN with variable degrees of necrosis, crescent formation,

Figure 23.7 Renal biopsy in Goodpasture's disease. **A**, Glomerulus from a patient with Goodpasture's disease showing a recent, mostly cellular crescent. **B**, Direct immunofluorescence study showing ribbon-like linear deposition of IgG along the glomerular basement membrane (GBM). The glomerular tuft is slightly compressed by cellular proliferation (exhibiting no immunofluorescence), forming a crescent (arrows). (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)

glomerulosclerosis, and tubular loss (Fig. 23.7). The degree of crescent formation and tubular loss correlates with renal prognosis. Characteristically, the crescents all appear to be of similar age and cellularity. When biopsy is performed earlier in the disease, changes may be limited to focal and segmental mesangial expansion, with or without necrosis. This progresses to hypercellularity and then to more general changes including fractures of the GBM and Bowman's capsule, neutrophils in the glomeruli, and glomerular capillary thrombosis.¹⁸

Immunohistology

In the presence of severe glomerular inflammation, linear deposition of immunoglobulin along the GBM is pathognomonic. The immunoglobulin is usually IgG, sometimes (10% to 15%) with IgA or IgM, but very rarely IgA alone is detected. Linear deposition of C3 is detectable in about 75% of biopsies. Linear immunofluorescence with anti-immunoglobulin reagents is occasionally seen in other conditions (Fig. 23.8), usually without glomerular inflammation. In most instances, the deposited immunoglobulin is less abundant than in Goodpasture's disease and is either nonspecifically deposited or bound to GBM components other than type IV collagen chains.

Circulating IgG anti-GBM antibodies are almost invariably present, even in the rare instances in which only IgM or IgA is demonstrated on the GBM. They may be detected and quantified by use of immobilized Goodpasture antigen in an immunoassay. The titer of anti-GBM antibody at presentation correlates

Conditions Associated with Linear Binding of Immunoglobulin to the GBM

Specific Binding to the GBM

Goodpasture's syndrome

Alport's syndrome after renal transplantation

Nonspecific Binding to the GBM

Diabetes

Cadaver kidneys

Light-chain disease

Fibrillary glomerulopathy

Systemic lupus erythematosus (possibly specific but not considered directly pathogenic)

Figure 23.8 Conditions associated with linear binding of immunoglobulin to the glomerular basement membrane (GBM).

with the severity of nephritis. Treatment and relapse are often mirrored by changes in titer.

Pathology in Other Tissues

Pathologic changes in lung tissue can be difficult to interpret because the changes, including immunoglobulin deposition, are often patchy and may be missed. Frequently, the only findings are mild, chronic inflammation and hemosiderin-laden macrophages, which are consistent with other more common pathologic diagnoses. This makes negative bronchoscopic or open lung biopsy findings unhelpful in excluding the diagnosis.

Other tissues in which $\alpha 3(\text{IV})\text{NC1}$ is expressed are rarely available for pathologic analysis, but if antibody is deposited in other sites, disease is rarely associated with it. A number of case reports describe neurologic syndromes, particularly convulsions, that might be related to antibody deposition in the choroid plexus (Fig. 23.9) but may have other explanations in patients with acute kidney injury. Other reports have described retinal detachment, in one instance with antibody deposition, but again this is rare.

DIFFERENTIAL DIAGNOSIS

Diagnosis of Goodpasture's disease in patients who present with Goodpasture's syndrome does not usually present difficulties once the possibility has been raised, although the urgency is often not appreciated. Direct immunofluorescence on renal tissue and assay for circulating anti-GBM antibodies are the most rapid techniques, and renal biopsy is always indicated. Diagnosis is often delayed when patients present with subacute disease affecting the lung or the kidney in isolation. Patients with subacute lung hemorrhage may never report hemoptysis and may present as cases of diffuse lung disease, of which there are many causes. Testing for hematuria is important.

Detection of Anti–Glomerular Basement Membrane Antibodies

Direct immunohistology using antibodies that are specific for different classes of immunoglobulin is very sensitive for detection of anti-GBM antibody production, as the GBM selectively

Figure 23.9 Direct immunofluorescence study showing binding of IgG to the choroid plexus of a patient who died of Goodpasture's disease. (Courtesy Dr. Stephen Cashman, Imperial College, London, UK.)

adsorbs and concentrates low levels of circulating antibody. However, in some circumstances, GBM may also adsorb antibody nonspecifically (see Fig. 23.8). Detection of anti-GBM antibodies in serum requires solid-phase immunoassays based on preparations of human or animal GBM or recombinant antigen. The quality of these assays is variable. Confirmation of the specificity of anti-GBM antibodies may be obtained by Western blotting of serum onto solubilized human GBM or recombinant $\alpha 3(\text{IV})\text{NC1}$, usually at a reference laboratory. Indirect immunohistology (putting patients' serum onto normal kidney sections) is too insensitive for reliable diagnostic use.

False-positive results may be encountered in sera from patients with inflammatory diseases that often exhibit increased non-specific binding. This places greater emphasis on the purity of antigen used for anti-GBM assays. False-negative results are usually encountered in patients with low titers of antibodies in association with isolated lung disease or with very early or subacute renal disease. Low titers may also be associated with anti-GBM disease that occurs after renal transplantation in patients with Alport's syndrome (see later discussion).

In very advanced disease, linear antibody deposition may not be seen because of extensive destruction of GBM structure. Otherwise, deposited immunoglobulin remains detectable for some months after immunoassays have become negative.

Patients with Anti–Glomerular Basement Membrane Antibodies and Other Diseases

Antineutrophil Cytoplasmic Antibody and Systemic Small-Vessel Vasculitis

Anti-GBM antibodies are sometimes detected in patients with antineutrophil cytoplasmic antibodies (ANCA), especially ANCA with specificity for myeloperoxidase (see Chapter 24). Such "double-positive" patients may have a clinical course and response to treatment more typical of vasculitis than of Goodpasture's disease and have possibly developed anti-GBM antibodies secondary to vasculitic glomerular damage.⁸⁻¹⁰ Anti-GBM titers tend to be lower in ANCA-positive anti-GBM antibody-positive patients than in patients with anti-GBM antibodies alone. Recovery of renal function may be more likely if ANCA are present, even if patients are dialysis dependent when treatment is started,

Non-Immune Causes of Pulmonary-Renal Syndrome
With Pulmonary Edema
Acute kidney injury with hypervolemia
Severe cardiac failure

Figure 23.10 Non-immune causes of pulmonary-renal syndrome.

although newer series have failed to detect the differences described in early reports.

Membranous Nephropathy

Anti-GBM antibodies are occasionally identified in patients with membranous nephropathy (MN), usually coincident with an accelerated decline in renal function and the formation of glomerular crescents.^{5,13,19} In approximately two thirds of the two dozen or so published reports, there was evidence of evolution from preexisting nephrotic syndrome, and in about half, a previous kidney biopsy showed typical MN. Progression to end-stage renal disease (ESRD) has usually been rapid, but the diagnosis has rarely been made at an early enough stage to expect intensive treatment to be successful. Three patients with Goodpasture's disease later developed typical MN.

Differential Diagnosis of Goodpasture's Syndrome

A wide variety of conditions may cause simultaneous pulmonary and renal disease. The term *pulmonary-renal syndrome* implies failure of both organs, the most common cause being fluid overload in a patient with renal failure of any cause. This may resemble Goodpasture's syndrome, particularly if there is hematuria and preexisting cardiac dysfunction. However, a number of diseases may mimic Goodpasture's syndrome (lung hemorrhage with RPGN) to varying degrees by causing acute kidney injury (AKI) with acute lung disease (Fig. 23.10). Diseases associated with the syndrome fall into two pathogenetic classes: those characterized by systemic vasculitis and those associated with anti-GBM antibodies (Goodpasture's disease; Fig. 23.11).

These diseases can sometimes be differentiated clinically, but serology and renal biopsy are usually required. Renal biopsy also provides valuable prognostic information.

NATURAL HISTORY

There is some variability in the pattern of early disease. Most patients present acutely with lung hemorrhage or advanced renal failure and report that the illness developed during only weeks

Causes of Lung Hemorrhage and Rapidly Progressive Glomerulonephritis
Diseases Associated with Antibodies to the GBM (20%–40% of cases)
Goodpasture's disease (spontaneous anti-GBM disease)
Diseases Associated with Systemic Vasculitis (60%–80% of cases)
Wegener's granulomatosis (common)
Microscopic polyangiitis
Systemic lupus erythematosus
Churg-Strauss syndrome
Henoch-Schönlein purpura
Behçet's syndrome
Essential mixed cryoglobulinemia
Rheumatoid vasculitis
Drugs: penicillamine, hydralazine, propylthiouracil

Figure 23.11 Causes of lung hemorrhage and rapidly progressive glomerulonephritis. GBM, glomerular basement membrane.

or a few months. However, there are several reports of patients presenting with mild respiratory symptoms or incidental microscopic hematuria with disease progressing much more slowly during months or years; some have abruptly developed the full acute syndrome.

Once RPGN has developed, renal function is rapidly and often irretrievably lost. Progression is often much more rapid than in RPGN occurring in other contexts, such as microscopic polyangiitis, perhaps because more glomeruli are simultaneously affected. Consequently, there is a much narrower window of opportunity for effective treatment.

Although a severe exacerbation of lung disease commonly coincides with deterioration of renal function, the natural history of isolated lung disease critically depends on continued exposure to irritants.

TREATMENT

Immunosuppressive Regimens

Before the introduction of immunosuppressive treatment, most patients died shortly after the development of renal impairment or lung hemorrhage.¹⁷ Now lung hemorrhage can usually be arrested within 24 to 48 hours. Renal function can be protected if impairment is mild, and even severe renal impairment can be reversed in some circumstances. However, dialysis-dependent patients rarely recover kidney function despite immunosuppression and should probably be immunosuppressed only if lung hemorrhage occurs.

A chart recording treatment of a patient with Goodpasture's disease is shown in Figure 23.12. Recommended treatment for acute severe disease is shown in Figure 23.13. It was devised to reduce levels of circulating pathogenic antibodies as rapidly as possible and to curtail their contribution to the rapid glomerular destruction that can occur during acute severe disease, but almost certainly it is effective through a much broader range of mechanisms including T-cell depletion. Once the disease is

controlled, immunosuppression can usually be tapered off during 3 months, and subsequent relapse is uncommon. The immune response is self-limited in the absence of immunosuppression, antibodies disappearing during 1 to 2 years. Spontaneous remissions and the effectiveness of relatively brief periods of immunosuppression are in striking contrast with the more prolonged immunosuppression generally required to prevent relapse of vasculitis and suggest that there is a greater capacity for the restoration of usual tolerance to $\alpha 3(IV)NC1^{20}$ than to targets in vasculitis.

In RPGN in which there is no evidence of an infective cause, immunosuppressive therapy should be started immediately, sometimes before the renal biopsy findings are available. If therapy is stopped after a few days, the patient will have incurred

very little risk (as long as pulse high-dose corticosteroids are avoided) but sometimes has a great deal to gain from earlier treatment.

Plasma Exchange and Immunosuppression

The regimen described in Figure 23.13 dramatically improved the outlook for patients when it was introduced in the 1970s. An early randomized trial²¹ suggested some additional benefit of plasma exchange, but the interpretation was complicated by the fact that the recipient group had less severe disease at presentation. It showed that milder disease can be effectively treated with corticosteroids and cyclophosphamide alone, although the overall outcomes for all patients were not as good as have been described with more intensive regimens.²¹ Historical evidence suggests that treatment with corticosteroids alone, or corticosteroids with azathioprine, is less effective. Plasma exchange is of value only if it is accompanied by adjunctive immunosuppressive therapy. Immunoabsorption to protein A also lowers anti-GBM antibodies rapidly; it does not deplete complement components or clotting factors, and a few reports suggest that it is as effective as plasma exchange. Information on the effectiveness of newer immunosuppressive agents such as mycophenolate mofetil (MMF) or anti-B cell antibodies (which tend to have only a slow effect on antibody production, but may affect antigen presentation), is lacking. Their use over proven therapy is rarely justifiable in this often very rapidly progressive disease. In contrast to advanced renal failure, in which treatment is unlikely to lead to recovery of renal function, even severe lung hemorrhage is likely to respond to treatment with full or nearly full recovery of lung function.

Lung hemorrhage occurring alone tends to be relapsing and remitting, so there have been many reports of treatments (including bilateral nephrectomy) that may help. Pulse methylprednisolone has been advocated, but high doses of corticosteroids fail to alter the underlying pathogenetic immune response and put the patient at increased risk of infective and other complications. We recommend treating seriously ill patients with moderate doses of corticosteroids plus plasma exchange and cyclophosphamide.

In other acute severe diseases, daily administration of cyclophosphamide has often been superseded by pulse administration. We still prefer to use daily oral administration because it is known to work and only 3 months of therapy is required. Patients

Figure 23.12 Response to immunosuppressive treatment in a patient with Goodpasture's disease. The patient required dialysis for renal disease but had no lung hemorrhage. The good response to treatment was unusual but not unique. The renal biopsy showed that 85% of glomeruli contained recent (mostly cellular) crescents, suggesting very acute disease, which may be indicative of a more favorable response to treatment.

Treatment Regimen for Acute Goodpasture's Disease	
Prednisolone	1 mg/kg/24 h orally. Reduce at weekly intervals to achieve one sixth of this dose by 8 weeks. For a starting daily dose of 60 mg, use weekly reductions to 45, 30, 25, 20, and 15 mg; then 2 weekly to 12.5 and 10 mg. Maintain this dose to 3 months; then taper to stop by 4 months.
Cyclophosphamide	3 mg/kg/24 h orally, rounded down to the nearest 50 mg. Patients >55 years receive a reduced dose of 2.5 mg/kg.
Plasma exchange	Daily exchange of 1 volume of plasma for 5% human albumin for 14 days or until the circulating antibody is suppressed. In the presence of pulmonary hemorrhage or within 48 hours of an invasive procedure, 300 to 400 ml of fresh frozen plasma is given at the end of each treatment or according to coagulation tests.
Monitoring	Daily blood count during plasma exchange and while antibody titer remains elevated. At least twice weekly during first month, weekly thereafter. If white blood cell count decreases to $<3.5 \times 10^9/l$, stop cyclophosphamide until the count recovers. Resume at lower dose if cessation has been necessary. Baseline DLCO, with further measurements as indicated. Daily coagulation tests during plasma exchange to monitor for significant depletion of clotting factors. Initially, daily checks of renal and hepatic function, glucose.
Prophylaxis against complications of treatment	Oral antifungal lozenges or rinse; proton pump inhibitor. Cotrimoxazole prophylaxis against <i>Pneumocystis carinii</i> . Avoid nonessential lines, catheters.

Figure 23.13 Treatment regimen for acute Goodpasture's disease.

Factors Influencing Decision to Treat or Not to Treat Aggressively in Goodpasture's Disease		
	Factors Favoring Aggressive Treatment	Factors Against Aggressive Treatment
Pulmonary hemorrhage	Present	Absent
Oliguria	Absent	Present
Creatinine	<5.5 mg/dl (approximately 500 μ mol/l)	>5.5–6.5 mg/dl (approximately 500–600 μ mol/l) and ANCA negative Severe damage on kidney biopsy No desire for early kidney transplantation
Other factors	Creatinine >5.5–6.5 mg/dl (approximately 500–600 μ mol/l) <i>but</i> Rapid and recent progression ANCA positive Glomerular damage less severe than expected Crescents recent, nonfibrous Early renal transplantation desired	
Associated disease	Absent	Unusually high risk from immunosuppression

Figure 23.14 Factors influencing decision to treat or not to treat aggressively in Goodpasture's disease. ANCA, antineutrophil cytoplasmic antibody.

unable to take the drug orally can be given daily intravenous therapy at the usual oral dose. Dose does not need to be reduced in severe renal failure provided the white blood cell count is monitored closely, but reductions for older patients are important (see Fig. 23.13), and close monitoring of leukocyte counts is imperative in all patients. If pulsed therapy were chosen, the CYCLOPS regimen would be a reasonable if untested option (see Chapter 24).

Results from all series show that recovery of renal function is unlikely if, at the time treatment is commenced, the patient is oliguric, has a very high proportion of glomeruli with circumferential crescents, or has a serum creatinine level above 5.5 to 6.5 mg/dl (about 500 to 600 μ mol/l).²² This is a notably different experience from that encountered in systemic vasculitis or idiopathic RPGN (see Chapter 24), in which renal disease of apparently similar severity (judged by histology and serum creatinine level) can be salvaged by similar treatment protocols.²³ It has led to the suggestion that immunosuppressive treatment should be withheld from patients in whom the chance of recovery is slight (Fig 23.14 and see later).

Supportive Treatment

The most likely cause of death in the first few days is respiratory failure caused by lung hemorrhage. Lung hemorrhage may be precipitated or exacerbated by:

- Fluid overload.
- Smoking and other pulmonary irritants, possibly including high fractional inspired oxygen concentrations.
- Local or distant infection.
- Anticoagulation used during dialysis or plasma exchange.
- Thrombocytopenia, defibrination, and depletion of clotting factors as a consequence of plasma exchange.

It is therefore sensible to ensure correct fluid balance, to prohibit smoking, to use the lowest fractional inspired oxygen concentration that gives adequate oxygenation, and to minimize the use of heparin.

Plasma exchange should be monitored by daily blood counts, calcium concentration (if regional citrate anticoagulation is used), and coagulation tests. Diminished clotting factor levels

should be replenished by administration of fresh frozen plasma or clotting factor preparations at the end of each plasma exchange session as required.

After the first few days, the major cause of morbidity and mortality is infection. Infection carries the added risk of potentiating glomerular and lung inflammation and injury, so precautions to reduce risk, such as minimizing indwelling cannulae, are important. If leukopenia below $3.5 \times 10^9/l$ or neutropenia develops, cyclophosphamide should be discontinued and resumed at a lower dose when the neutrophil count recovers, if necessary with the assistance of granulocyte colony-stimulating factor.

Monitoring Effect of Treatment on Disease Activity

The effect of treatment on the renal disease is monitored by following serum creatinine values. Indicators of recent lung hemorrhage include hemoptysis, decreases in hemoglobin concentration, chest radiograph changes, and increases in the DLco, the last being the most sensitive. Any worsening of symptoms during treatment may indicate inadequate immunosuppression, but it is frequently a consequence of intercurrent infection exaggerating immunologic injury or fluid overload or other factors precipitating lung hemorrhage.

Monitoring of anti-GBM titers during and particularly 24 hours after the last planned plasma exchange treatment is useful for confirming effective suppression of autoantibodies. They should be undetectable within 8 weeks, but even without treatment, they generally become undetectable by an average of 14 months.

Duration of Treatment and Relapses

Corticosteroid treatment may be gradually reduced and cyclophosphamide discontinued at 3 months. In contrast with the treatment of small-vessel vasculitis, it is not usually necessary to continue immunosuppression for longer than this. Longer treatment is appropriate for patients who are both anti-GBM antibody positive and ANCA positive (see later discussion). Late increases in anti-GBM level may predict clinical relapse, although

antibodies are generally permanently suppressed in patients who have completed the immunosuppressive regimen. If there is recurrence, success has been achieved by treating as at first presentation.

Electing Not to Treat

Advanced renal failure, frequently already established at presentation, is generally not salvaged by any current treatment.^{22,24,25} Furthermore, the immunosuppressive regimen outlined carries significant risks, and careful monitoring is required. For these reasons, it may be reasonable not to commence immunosuppression in patients who present with advanced renal failure without lung hemorrhage. The decision not to treat is strengthened if the renal biopsy specimen shows widespread glomerulosclerosis and tubular loss and the patient is dialysis dependent at presentation (see Fig. 23.14). The risk for development of late lung hemorrhage in these circumstances seems to be low but warrants particular care to avoid the major precipitating factors, smoking and pulmonary edema, in at least the first few months.

However, patients who are dialysis dependent should usually be treated if the renal histopathologic changes are unexpectedly mild or very recent (highly cellular crescents, even if 100% of glomeruli are involved, or acute tubular necrosis). Several reports describe good outcomes in these circumstances even after prolonged oliguria.

Treatment of Double-Positive Patients

Patients with both ANCA and anti-GBM antibodies may have other extrarenal disease requiring treatment (see Fig. 23.14). There is conflicting evidence as to whether their renal prognosis is the same as or better than that of other patients with anti-GBM antibodies. Earlier series suggested a better prognosis, but this was not confirmed in two later reports.^{11,12} Because of the risk of serious disease in other organs, double-positive patients should usually receive an immunosuppressive regimen similar to that given for small-vessel vasculitis with continuing immunosuppression with azathioprine after 3 months of cyclophosphamide (see Chapter 24).

TRANSPLANTATION

Renal transplantation in patients who have had Goodpasture's disease carries the additional risk of disease recurrence. Recurrence with consequent loss of the graft has been reported and appears more likely when circulating anti-GBM antibodies are still detectable at the time of transplantation. For this reason, it is reasonable to delay transplantation until circulating anti-GBM antibodies have been undetectable for 6 months and to monitor graft function, urinary sediment, and circulating anti-GBM antibody levels to detect recurrent disease (see Chapter 104). Biopsies of well-functioning grafts sometimes show linear deposition of immunoglobulin on the GBM without clinical or histologic disease or apparently an adverse prognosis.

ALPORT'S SYNDROME POST-TRANSPLANT ANTI-GLOMERULAR BASEMENT MEMBRANE DISEASE

Patients with Alport's syndrome have mutations in a gene encoding one of the tissue-specific type IV collagen chains, usually $\alpha 5$. Because these chains assemble with each other during biosynthesis, the resulting phenotype in the case of most mutations often

has all the tissue-specific chains ($\alpha 3$ through $\alpha 5$) missing from the basement membranes, where they are normally coexpressed. Altered expression may lead to absent or inadequate immunologic tolerance to these proteins and to the preservation of the capacity to mount a powerful (allo)immune response to the type IV collagen chains expressed in a normal donor kidney after renal transplantation. Most Alport's syndrome patients accommodate renal transplants with conventional immunosuppression without development of anti-GBM nephritis. However, the development of low titers of anti-GBM antibodies is shown by the fact that many such patients have linear deposition of IgG on the GBM of the transplanted kidney by direct immunofluorescence, without disease. This alone does not justify treatment.

Up to 5% of Alport patients develop RPGN in the transplanted kidney. It is clinically indistinguishable from Goodpasture's syndrome but without lung hemorrhage. This is more likely if they have a large gene deletion causing the disease rather than a point mutation, with the inference that their immune system has never been exposed to the mature protein. Typically, graft function is lost despite treatment for presumed acute rejection. Disease is usually encountered some months or longer after a first renal transplant, after weeks in a second, and after days in a third.²⁶ However, regrafting has been successful in two cases known to us and in two further cases in the literature. If the disease is recognized early, there are sound theoretical reasons for treating with the regimen recommended for Goodpasture's syndrome, but there are few data on its effectiveness.²⁶

In contrast to spontaneous Goodpasture's syndrome, the specificity of anti-GBM antibodies in Alport's post-transplant anti-GBM disease is not always to $\alpha 3(\text{IV})\text{NC1}$. In many patients, possibly in most, the autoantibodies are specific for $\alpha 5(\text{IV})\text{NC1}$, encoded by the *COL4A5* gene usually implicated in causation of the disease.²⁷ This is important because immunoassays for anti-GBM antibodies are optimized for detection of the anti- $\alpha 3(\text{IV})\text{NC1}$ antibodies of spontaneous Goodpasture's syndrome, and they may have low sensitivity for anti- $\alpha 5(\text{IV})\text{NC1}$ antibodies. In the absence of widely available assays for these uncommon antibodies, renal biopsy with immunohistology is the only reliable method of diagnosis.

Renal and Systemic Vasculitis

J. Charles Jennette, Ronald J. Falk

DEFINITION

The kidneys are targets for a variety of systemic vasculitides, especially those that affect small vessels.¹⁻⁵ This is not surprising given the large number and variety of renal vessels. Vasculitis involving the kidneys can produce a wide variety of clinical manifestations, depending in large measure on the type of renal vessel affected. As demonstrated in [Figures 24.1 to 24.3](#), vasculitides can be categorized as large-vessel vasculitis, medium-sized vessel vasculitis, and small-vessel vasculitis. The categorization of systemic vasculitides is controversial. For the purposes of the discussion in this chapter, the Chapel Hill Consensus Conference definitions are used (see [Fig. 24.3](#)).⁴

A number of the vasculitides listed in [Figure 24.2](#) are covered elsewhere in the book and are not reviewed in detail here except in the context of differential diagnosis, for example, cryoglobulinemic vasculitis (see Chapter 55), Henoch-Schönlein purpura (HSP) (see Chapter 22), and anti-glomerular basement membrane (GBM) disease (see Chapter 23). Nephrologists most often encounter patients with small-vessel vasculitides because they often cause glomerulonephritis (GN); thus, these receive the most attention in this chapter.

Small-Vessel Vasculitis

Small-vessel vasculitis is necrotizing polyangiitis that affects predominantly vessels smaller than arteries, including capillaries, venules, and arterioles; however, arteries also may be involved. The most common renal targets for small-vessel vasculitides are the glomeruli, and therefore the most common clinical renal manifestations are those of GN.

Medium-Sized Vessel Vasculitis

Medium-sized vessel vasculitis is necrotizing arteritis that affects predominantly major visceral arteries. The interlobar arteries and arcuate arteries are affected most often, although the interlobular arteries and main renal artery may be affected. Inflammation and necrosis of arteries may result in thrombosis or rupture, which causes renal infarction and hemorrhage, respectively.

Large-Vessel Vasculitis

Large-vessel vasculitis is chronic granulomatous arteritis that affects predominantly the aorta and its major branches. When there is renal involvement, the ostia of the renal arteries and the

main renal arteries are most often affected. The most common clinical renal manifestation is renovascular hypertension.

SMALL-VESSEL PAUCI-IMMUNE VASCULITIS

Wegener's granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis share an indistinguishable form of necrotizing small-vessel vasculitis that affects capillaries, venules, arterioles, and small arteries.¹⁻⁴ Some patients, however, have no evidence of involvement of arteries, even though they have involvement of glomerular capillaries, causing GN; pulmonary alveolar capillaries, causing pulmonary hemorrhage; or dermal venules, causing purpura. These so-called pauci-immune small-vessel vasculitides are distinguished from clinically and histologically similar forms of immune complex small-vessel vasculitis, such as cryoglobulinemic vasculitis and HSP, by the absence or paucity of immune complex deposits in vessel walls. The diagnosis for the specific subtypes of pauci-immune small-vessel vasculitides can be made on the basis of the accompanying syndrome.⁴

- Wegener's granulomatosis occurs in association with necrotizing granulomatous inflammation, which most often affects the respiratory tract.
- Churg-Strauss syndrome is vasculitis occurring in association with asthma, eosinophilia, and necrotizing granulomatous inflammation.
- Microscopic polyangiitis is pauci-immune systemic vasculitis occurring in the absence of evidence of Wegener's granulomatosis or Churg-Strauss syndrome, that is, in the absence of asthma and eosinophilia and with no evidence of necrotizing granulomatous inflammation.

Microscopic polyangiitis, Wegener's granulomatosis, and, less frequently, Churg-Strauss syndrome also share an indistinguishable pattern of GN that is the expression of the vasculitis in glomerular capillaries.^{1,2} The GN usually has necrosis and crescent formation and an absence or paucity of immunoglobulin deposition and is often designated pauci-immune crescentic GN. When pauci-immune crescentic GN occurs in the apparent absence of systemic vasculitis, it is sometimes referred to as renal vasculitis, renal-limited vasculitis, or idiopathic rapidly progressive GN (RPGN).

Pathogenesis

Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, and isolated pauci-immune crescentic GN are all associated with the presence in serum of autoantibodies

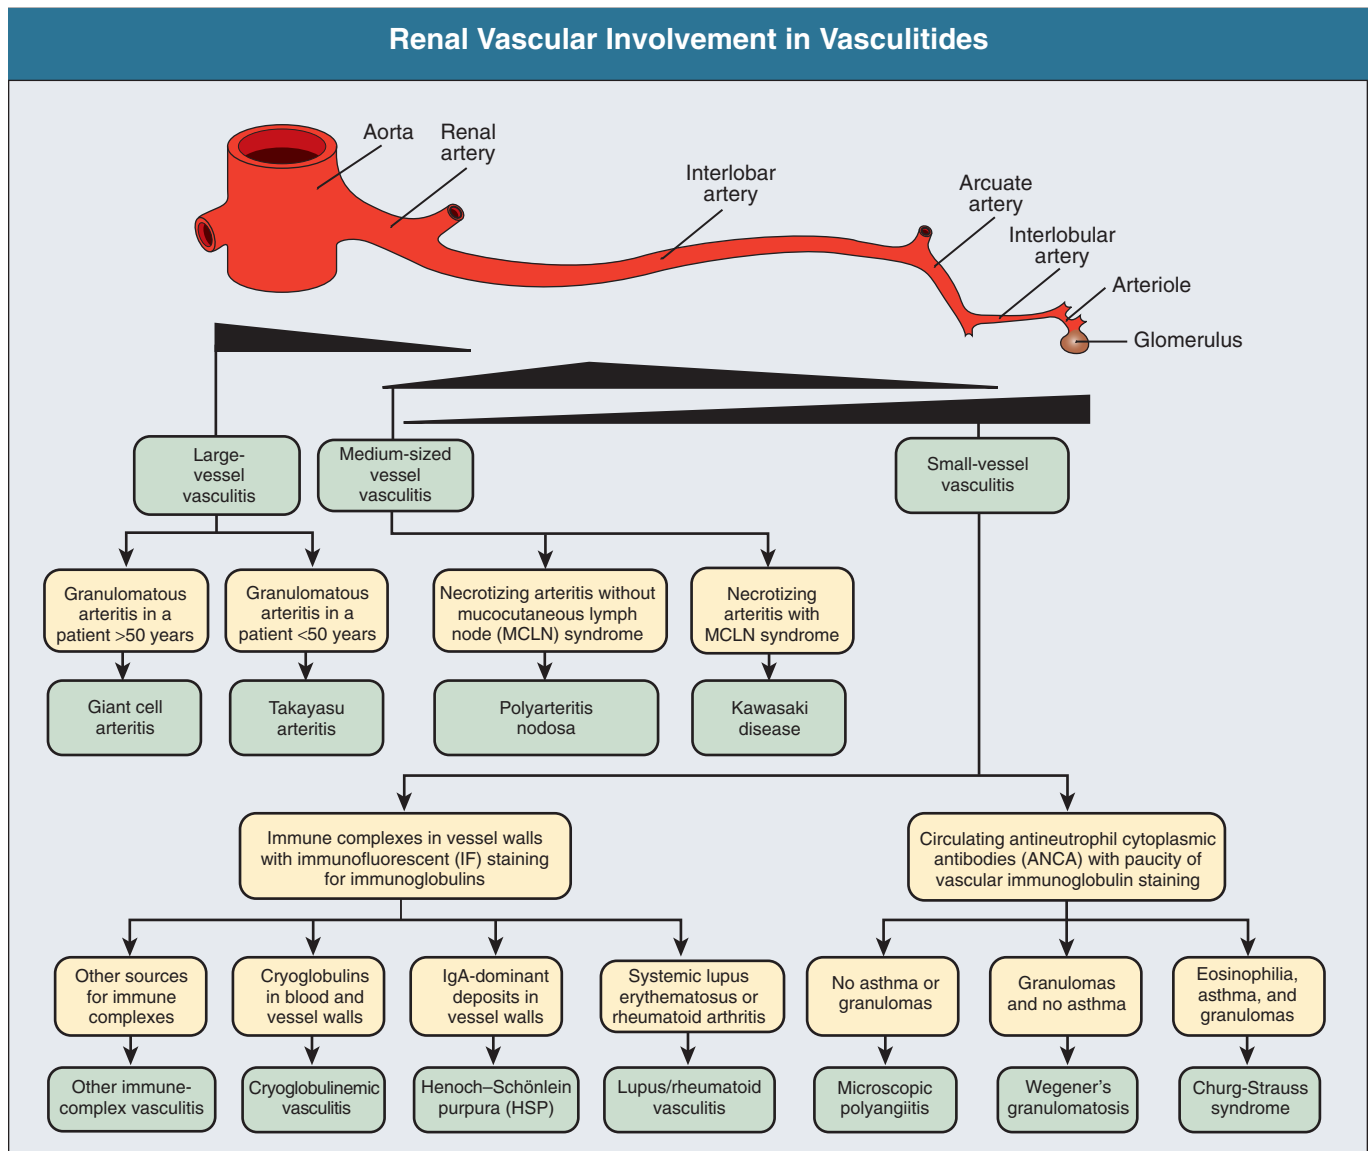

Figure 24.1 Renal vasculitis: the predominant distribution of renal vascular involvement by a variety of vasculitides. The heights of the trapezoids represent the relative frequency of involvement of different portions of the renal vasculature by the three major categories of vasculitis. (Modified from reference 3.)

against components of the cytoplasm of neutrophils: circulating antineutrophil cytoplasmic antibodies (ANCA).⁶⁻⁹ The most common antigen specificities of ANCA in patients with vasculitis and GN are for proteinase 3 (PR3) and myeloperoxidase (MPO).

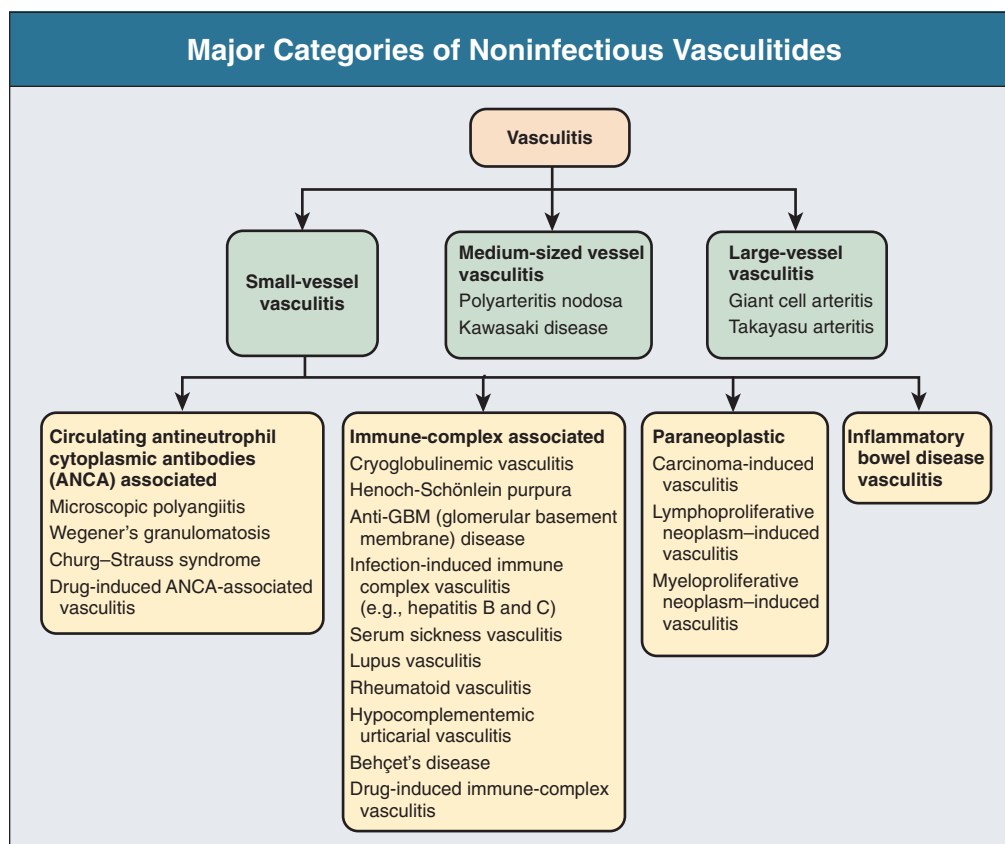

The strong association of ANCA with a distinctive form of small-vessel vasculitis raises the possibility that ANCA are involved in the pathogenesis.⁶ The observation that ANCA titers correlate with disease activity is more suggestive; however, this is not a very tight correlation.^{7,8} Even more supportive of a pathogenetic link is the observation that administration of certain drugs, such as propylthiouracil, hydralazine, and penicillamine, can induce ANCA in the circulation concurrent with the development of pauci-immune crescentic GN and small-vessel vasculitis.¹⁰ Most compelling of all is the report of a neonate who developed GN and pulmonary hemorrhage apparently caused by transplacental passage of MPO-ANCA IgG.¹¹

The ability of ANCA IgG to cause pauci-immune necrotizing and crescentic GN and vasculitis has been demonstrated in a

mouse model. Wild-type or immunodeficient mice that receive anti-MPO antibodies intravenously develop pauci-immune focal necrotizing GN with crescents.¹² This GN is mediated by neutrophil activation and can be prevented by neutrophil depletion.¹³ A rat model of pauci-immune necrotizing and crescentic GN has been developed by immunizing rats with human MPO, resulting in the development of antibodies that cross-react with rat MPO and are able to induce pauci-immune glomerular necrosis and crescents.¹⁴

A number of *in vitro* observations suggest mechanisms by which ANCA can cause vascular injury. Priming of neutrophils by cytokines, as would occur with a viral infection, causes neutrophils to increase expression of ANCA antigens on their surfaces, where they are accessible to interact with ANCA. Cytokine-primed neutrophils that are exposed to ANCA release IgG from granules, release toxic oxygen metabolites, and kill cultured endothelial cells.^{6,15-17} ANCA-antigen complexes adsorb onto endothelial cells, where they could participate in *in situ*

Figure 24.2 The major categories of noninfectious vasculitis. Not included are vasculitides that are known to be caused by direct invasion of vessel walls by infectious pathogens, such as rickettsial vasculitis and neisserial vasculitis.

immune complex formation.¹⁸ ANCA activation of neutrophils is mediated by both F(ab)₂ binding to neutrophils and Fc receptor engagement.^{19,20} Neutrophils that have been activated by ANCA adhere to endothelial cells and release mediators of inflammation and cell injury.^{14,16,17} Activation of the alternative complement pathway may play a role in amplifying ANCA-induced inflammation.²¹ If these events occurred *in vivo*, they would lead to vasculitis as a result of neutrophils adhering to, penetrating, and destroying vessel walls (Fig. 24.4).²²

Thus, the clinical and the experimental animal data support the hypothesis that ANCA can activate neutrophils and cause vasculitis, especially if there is a concurrent synergistic proinflammatory stimulus. The requirement for a synergistic inflammatory process may be reflected in the very frequent association of the onset of ANCA small-vessel vasculitis with an influenza-like syndrome.²³ An influenza-like syndrome is a manifestation of high levels of circulating cytokines that could serve as priming factors for neutrophils.

Epidemiology

Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome usually begin during the fifth, sixth, and seventh decades of life, although they may occur at any age. There is a slight male predominance. The incidence is disproportionately greater in Caucasians than in African Americans. In Europe, microscopic polyangiitis has a prevalence of approximately 2.5/100,000; Wegener's granulomatosis, 2.5/100,000; and Churg–Strauss syndrome, 1/100,000.²⁴ Although it is not fully documented, there is a suspicion that Wegener's granulo-

matosis is more frequent in colder compared with warmer climates, whereas microscopic polyangiitis has the opposite trend.²⁴

Clinical Manifestations

The clinical manifestations of Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome are extremely varied because they are influenced by the sites of involvement and the activity versus the chronicity of involvement. All three categories of vasculitis share features caused by the small-vessel vasculitis, and patients with Wegener's granulomatosis and Churg–Strauss syndrome have the additional features that define each of these syndromes.^{2,4,5,7,8,23,25,26}

Renal involvement is very common in Wegener's granulomatosis and microscopic polyangiitis and less frequent in Churg–Strauss syndrome (Fig. 24.5).² The most common renal manifestations are caused by glomerular involvement and include hematuria, proteinuria, and renal failure. The renal failure often has the characteristics of RPGN in patients with Wegener's granulomatosis and microscopic polyangiitis but usually is less severe in those with Churg–Strauss syndrome. Wegener's granulomatosis and microscopic polyangiitis also can present as a subacute or chronic nephritis. A cohort of more than 300 pauci-immune crescentic GN patients evaluated at the time of renal biopsy had a mean age of 56 ± 20 years (range, 2 to 92 years), male-to-female ratio of 1.0:0.9, mean serum creatinine concentration of 6.5 ± 4.0 mg/dl (range, 0.8 to 22.1 mg/dl), and proteinuria of 1.94 ± 2.95 g/dl (range, 0.11 to 18.00 g/dl).²⁷

Names and Definitions of Vasculitis Adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis

Category	Type	Definition
Large-vessel vasculitis	Giant cell (temporal) arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. Often involves the temporal artery. Usually occurs in patients older than 50 and often is associated with polymyalgia rheumatica.
	Takayasu arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 50.
Medium-sized vessel vasculitis	Polyarteritis nodosa (classic polyarteritis nodosa) Kawasaki disease	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis (GN) or vasculitis in arterioles, capillaries, or venules. Arteritis involving large, medium-sized, and small arteries and associated with mucocutaneous lymph node syndrome. Coronary arteries are often involved. Aorta and veins may be involved. Usually occurs in children.
Small-vessel vasculitis	Wegener's granulomatosis	Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels (e.g., capillaries, venules, arterioles, and arteries. Necrotizing GN is common).
	Churg-Strauss syndrome	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels; associated with asthma and blood eosinophilia.
	Microscopic polyangiitis (microscopic polyarteritis)	Necrotizing vasculitis with few or no immune deposits affecting small vessels (i.e., capillaries, venules, arterioles). Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing GN is very common. Pulmonary capillaritis often occurs.
	Henoch-Schönlein purpura	Vasculitis with IgA-dominant immune deposits affecting small vessels (i.e., capillaries, venules, arterioles). Typically involves skin, gut, and glomeruli and is associated with arthralgias or arthritis.
	Essential cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits, affecting small vessels (i.e., capillaries, venules, arterioles); associated with cryoglobulins in serum. Skin and glomeruli are often involved.
	Cutaneous leukocytoclastic angiitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or GN.

Figure 24.3 Names and definitions of vasculitis adopted by the Chapel Hill Consensus Conference on the nomenclature of systemic vasculitis. Note that all three categories affect arteries, but only small-vessel vasculitis has a predilection for vessels smaller than arteries. (Modified from reference 22.)

Generalized nonspecific manifestations of systemic inflammatory disease, such as fever, malaise, anorexia, weight loss, myalgias, and arthralgias, often are present. As noted earlier, many patients trace the onset of their disease to an influenza-like illness.²³

Cutaneous involvement is frequent. Purpura is a common manifestation of Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome (Fig. 24.6). The purpura is most common on the lower extremities and tends to occur as recurrent crops. The purpura may be accompanied by small areas of ulceration. Nodular cutaneous lesions are much more frequent in Wegener's granulomatosis and Churg-Strauss syndrome than in microscopic polyangiitis. Nodules can be caused by dermal or subcutaneous arteritis and by the necrotizing granulomatous inflammation.

Upper and lower respiratory tract involvement is most common in Wegener's granulomatosis and Churg-Strauss syndrome but also occurs in those with microscopic polyangiitis. All three categories can have pulmonary hemorrhage caused by hemorrhagic alveolar capillaritis. Wegener's granulomatosis and Churg-Strauss syndrome also can have pulmonary injury caused by necrotizing granulomatous inflammation, which may be detected radiographically as nodular or cavitating lesions. By definition, patients with microscopic polyangiitis do not have granulomatous respiratory tract lesions.⁴

Manifestations of upper respiratory tract disease include subglottic stenosis, sinusitis, rhinitis, otitis media, and ocular inflammation. These features are most common in Wegener's granulomatosis but may occur in Churg-Strauss syndrome and microscopic polyangiitis. The upper respiratory tract inflammation in microscopic polyangiitis is caused by angiitis alone, without granulomatous inflammation. Destruction of bone, for example, resulting in septal perforation and saddle nose deformity, appears to require necrotizing granulomatous inflammation and therefore does not occur in microscopic polyangiitis.

Cardiac disease is identified in approximately 50% of patients with Churg-Strauss syndrome but in less than 20% of patients with Wegener's granulomatosis or microscopic polyangiitis. Manifestations range from transient heart block and ventricular hypokinesia that respond to immunosuppressive treatment to infarction and severe life-threatening myocarditis. Pericarditis and endocarditis also may occur.

Peripheral neuropathy, usually with a mononeuritis multiplex pattern, is the most common neurologic manifestation and is most frequent in Churg-Strauss syndrome. Central nervous system involvement is less common and most often is manifested as vasculitis within the meninges. Gastrointestinal involvement typically causes abdominal pain and blood in the stool, with mesenteric ischemia and, rarely, intestinal perforation. Vasculitis

in the pancreas and liver can mimic pancreatitis and hepatitis symptomatically.

Antineutrophil Cytoplasmic Autoantibodies

Serologic testing for ANCA is a useful diagnostic procedure for pauci-immune small-vessel vasculitis and pauci-immune crescentic GN but should be interpreted in the context of other characteristics of the patient.^{7,8,28-31} Laboratory testing for ANCA should include both indirect immunofluorescence microscopy assay (IFA) and enzyme immunoassay (EIA).³⁰

IFA using normal human neutrophils as substrate produces two major staining patterns (Fig. 24.7): cytoplasmic (c-ANCA), in which staining occurs diffusely throughout the cytoplasm, and perinuclear (p-ANCA). By EIA, most c-ANCA have specificity for PR3 (PR3-ANCA), and most p-ANCA have specificity for MPO (MPO-ANCA). For adequate diagnostic accuracy, all serologic testing for ANCA should include an immunochemical analysis for antigen specificity, such as an EIA.³⁰ Although positive results are rare in completely healthy individuals, approximately one fourth of patients with other inflammatory renal diseases (especially lupus) will have a

false-positive IFA result (usually with a p-ANCA pattern), and approximately 5% will have a false-positive EIA result (usually at low titer).³¹

ANCA testing has good sensitivity for pauci-immune small-vessel vasculitis and GN (80% to 90%). The specificity and predictive value depend on the population of patients.²⁹ Although ANCA are most frequent in patients with pauci-immune crescentic GN, approximately one fourth to one third of patients with anti-GBM crescentic GN and one fourth of patients with idiopathic immune-complex crescentic GN are ANCA positive.^{27,32} Patients with concurrent ANCA and anti-GBM antibodies have a worse prognosis than that of patients with ANCA alone.

Figure 24.8 provides an estimate of the relative frequencies of PR3-ANCA/c-ANCA and MPO-ANCA/c-ANCA in the different clinical phenotypes of pauci-immune small-vessel vasculitis and crescentic GN. PR3-ANCA/c-ANCA are most prevalent in Wegener's granulomatosis, and MPO-ANCA/p-ANCA are most prevalent in renal-limited pauci-immune crescentic GN. Patients with microscopic polyangiitis have a more even distribution of PR3-ANCA/c-ANCA and MPO-ANCA/p-ANCA.

Figure 24.6 Cutaneous vasculitis. Ankle of a patient with small-vessel vasculitis, showing purpura and a few small ulcers.

Patients with Churg-Strauss syndrome have the lowest overall frequency of ANCA, but the frequency of ANCA is much higher in patients with GN (75%) compared with those with no GN (26%).³³ These data make it clear that ANCA antigen specificity cannot be used to determine the clinicopathologic phenotype of pauci-immune small-vessel vasculitis.

Changes in ANCA titers over time correlate to a degree with disease activity but are not infallible markers and thus must be interpreted with much caution.^{7,8,30,34} In general, titers usually decrease with treatment and increase before or at the time of

Figure 24.7 Indirect immunofluorescence for antineutrophil cytoplasmic antibodies (ANCA). Antineutrophil Cytoplasmic Antibodies (ANCA) in Small-Vessel Vasculitis

	Frequency (%)		
	Proteinase 3 (PR3/c-ANCA)	Myeloperoxidase (MPO/p-ANCA)	Negative
Wegener's granulomatosis	70	25	5
Microscopic polyangiitis	40	50	10
Churg-Strauss syndrome	10	60	30
Pauci-immune glomerulonephritis (GN)	20	70	10

Figure 24.8 Antineutrophil cytoplasmic antibodies (ANCA) in small-vessel vasculitis. Approximate frequency of ANCA with specificity for proteinase 3 (PR3/c-ANCA) and for myeloperoxidase (MPO/p-ANCA) in patients with different categories of pauci-immune small-vessel vasculitis and crescentic glomerulonephritis.

disease recurrence. An increase in ANCA titer should prompt careful evaluation of the patient for corroborating evidence of exacerbation, but most physicians do not modify treatment on the basis of an increase in titer without accompanying clinical or laboratory evidence for increased disease activity.

Approximately 10% to 20% of patients with pauci-immune necrotizing and crescentic GN and small-vessel vasculitis will be ANCA negative. The clinical, pathologic, and outcome characteristics of these patients are no different from those of ANCA-positive patients.³⁵

ANCA may sometimes be positive with other inflammatory conditions that may need to be considered in the differential diagnosis, including inflammatory bowel disease, rheumatoid disease, chronic inflammatory liver disease, bacterial endocarditis, and cystic fibrosis.⁷ In this setting, specificity of the ANCA may not be against PR3 or MPO but against other neutrophil antigens, including lactoferrin, cathepsin G, and anti-bactericidal/permeability-increasing protein.

Pathology

The basic shared acute vascular lesion of the pauci-immune small-vessel vasculitides is segmental fibrinoid necrosis, often accompanied by leukocyte infiltration and leukocytoclasia (leukocyte fragmentation; Figs. 24.9 and 24.10).^{1,2,36,37} The earliest vasculitic lesions have infiltrating neutrophils that are quickly replaced by predominantly mononuclear leukocytes. The acute necrotizing lesions evolve into sclerotic lesions and may be complicated by thrombosis.

These focal necrotizing lesions can affect many different vessels, thus causing many different signs and symptoms. For example, involvement of glomerular capillaries causes nephritis; of alveolar capillaries, pulmonary hemorrhage; of dermal venules, purpura; of upper respiratory tract mucosal venules, rhinitis and sinusitis; of abdominal visceral arteries, abdominal pain; and of epineural arteries, mononeuritis multiplex.

The shared glomerular lesion of the pauci-immune small-vessel vasculitides is a necrotizing GN, usually with resultant crescent formation (Figs. 24.11 and 24.12).^{1,2,36,37} Early mild

Figure 24.9 Necrotizing arteritis in an interlobular artery from a patient with antineutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitis. There is segmental fibrinoid necrosis with adjacent perivascular leukocyte infiltration. (Hematoxylin-eosin; original magnification $\times 50$.)

Figure 24.10 Necrotizing arteritis in an interlobular artery from a patient with antineutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitis. The fibrinoid necrosis is accentuated by the red staining of the trichrome stain. (Masson trichrome; original magnification $\times 100$.)

Figure 24.11 Segmental glomerular necrosis and crescent formation in a patient with antineutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitis. The fibrinoid material is red. The uninvolved segments appear normal. (Masson trichrome; original magnification $\times 150$.)

Figure 24.12 Global glomerular necrosis and circumferential crescent formation in a glomerulus from a patient with antineutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitis. (Masson trichrome; original magnification $\times 150$.)

Figure 24.13 Medullary leukocytoclastic angiitis involving the vasa recta in a patient with Wegener's granulomatosis. (Hematoxylin-eosin; original magnification $\times 150$.)

lesions have segmental fibrinoid necrosis with or without an adjacent small crescent (see Fig. 24.11). Severe acute lesions may have essentially global necrosis with large circumferential crescents (see Fig. 24.12). In a cohort of 181 renal biopsy specimens from patients with ANCA-associated GN, 89.5% had glomerular crescents that on average affected 49% of glomeruli, with half having crescents in more than 50% of glomeruli.²⁷ Non-necrotic segments within segmentally injured glomeruli (see Fig. 24.11) and glomeruli without necrosis typically have slight or no histologic abnormalities.

As mentioned previously, approximately one fourth of patients with anti-GBM crescentic GN and one fourth of patients with immune complex-mediated crescentic GN will be ANCA positive.²⁷ By contrast, less than 5% of patients with immune complex GN who do not have crescents will be ANCA positive. Therefore, even in patients with immune complex GN, the presence of ANCA is associated with an increased incidence of crescents (and also inflammation in vessels other than glomerular capillaries).

In addition to GN, patients with pauci-immune small-vessel vasculitis also may have renal arteritis, most often affecting interlobular arteries (see Figs. 24.9 and 24.10), and medullary angiitis affecting the vasa recta (Fig. 24.13).^{1,2,36,37} The medullary angiitis may be severe enough to cause papillary necrosis, although this appears to be a rare complication.

Patients with Wegener's granulomatosis and Churg-Strauss syndrome have pathologic lesions in addition to the necrotizing small-vessel vasculitis that they have in common with microscopic polyangiitis patients.¹⁻⁴ The necrotizing granulomatous inflammation of Wegener's granulomatosis occurs most often in the respiratory tract and is characterized by zones of necrosis surrounded by mixed infiltrates of neutrophils, lymphocytes, monocytes, and macrophages, often including scattered multinucleated giant cells. Varying numbers of eosinophils may be present in the lesions of Wegener's granulomatosis, but these are more conspicuous in the necrotizing granulomatous inflammation of Churg-Strauss syndrome. Eosinophils also are typically conspicuous in the vasculitic lesions of Churg-Strauss syndrome, but this is not a pathognomonic observation because numerous eosinophils may be present in the vasculitic lesions of Wegener's granulomatosis, microscopic polyangiitis, polyarteritis nodosa, and other vasculitides.

Differential Diagnosis

ANCA-associated small-vessel vasculitis must be differentiated from other forms of small-vessel vasculitis that can produce the same signs and symptoms.² In addition, an attempt should be made to distinguish between microscopic polyangiitis, Wegener's granulomatosis, and Churg-Strauss syndrome, although sometimes this cannot be accomplished conclusively and is not required for initiation of therapy. Pathologic confirmation of the granulomatous inflammation that is seen in ANCA disease is particularly difficult because small biopsy specimens often show only nonspecific acute and chronic inflammation and necrosis. Thus, findings other than histologic lesions, such as nodular or cavitary lung lesions observed radiographically or destructive bone lesions in the nasal septum, often must be used as markers of necrotizing granulomatous inflammation to categorize patients. Because of the toxicity of the treatment, even in a patient with substantial clinical and serologic evidence of ANCA disease, pathologic confirmation of vasculitis is warranted. This can be accomplished with biopsy of many different involved sites, including skin, muscle, nerve, gut, and kidney. When there is substantial renal involvement, renal biopsy findings also can be useful for predicting the response to treatment and clinical outcome.³⁶⁻⁴⁰

All forms of small-vessel vasculitis listed in Figure 24.2 are capable of producing clinically indistinguishable overlapping features of disease, such as nephritis, purpura, peripheral neuropathy, myalgias, arthralgias, and abdominal pain. Figure 24.14 indicates a number of features that help discriminate between several important categories of small-vessel vasculitis.² Accurate differentiation among them is very important for proper patient management because the natural histories and appropriate treatments vary greatly. For example, a patient presenting with nephritis, arthralgias, and abdominal pain could have HSP, microscopic polyangiitis, cryoglobulinemic vasculitis, or a number of other small-vessel vasculitides. A number of serologic and pathologic observations are useful for reaching the correct diagnosis (see Fig. 24.14). A positive ANCA assay (confirmed by EIA to be MPO-ANCA or PR3-ANCA) supports a diagnosis of microscopic polyangiitis or one of the other pauci-immune small-vessel vasculitides. A negative ANCA assay and positive cryoglobulin assay (especially accompanied by hypocomplementemia and positive hepatitis C serology) support a diagnosis of cryoglobulinemic vasculitis. A negative ANCA assay, negative cryoglobulin assay, and normal complement levels support a diagnosis of HSP, especially in a patient younger than 21 years. The age of a patient influences the likelihood of a specific diagnosis. For example, approximately 80% of children younger than 10 years who have purpura, nephritis, and arthralgias will have HSP, whereas approximately 80% of adults older than 60 years with the same symptoms will have an ANCA-associated small-vessel vasculitis. However, each disease can occur at any age.

Exposure to drugs that may provoke ANCA vasculitis must be considered, including penicillamine, hydralazine, and propylthiouracil.¹⁰ Cholesterol embolization (see Chapter 64) can also mimic the clinical features of small-vessel vasculitis, but ANCA assay is negative. The differential diagnosis of lung hemorrhage and nephritis is discussed further in Chapter 23.

Recently, autoantibodies to lysosomal membrane protein 2 (LAMP-2) were reportedly identified in the circulation of most patients with either MPO-ANCA or PR3-ANCA.⁴¹ LAMP-2 has homology to the bacterial adhesin FimH, and thus

Differential Diagnostic Features of Selected Forms of Small-Vessel Vasculitis

Asthma and eosinophilia	—	—	+	—	—

Figure 24.14 Differential diagnostic features of selected forms of small-vessel vasculitis. *All these vessel vasculitides can manifest any of the shared features of small-vessel vasculitides, such as nephritis, purpura, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence and, just as important, by the absence of certain specific features. (Modified from reference 2.)

autoantibodies to LAMP-2 may arise by molecular mimicry secondary to infection with fimbriated gram-negative bacteria. Further, rats injected with anti-LAMP-2 or immunized with FimH develop pauci-immune focal necrotizing and crescentic GN. If these exciting observations are confirmed, anti-LAMP-2 antibodies will be a useful marker for pauci-immune small-vessel vasculitis but also may prove to be critically important in the pathogenesis of pauci-immune vasculitis and GN.

Natural History

Before the advent of immunosuppressive therapy, the survival of patients with Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome was dismal, with most patients dying in less than a year. With adequate immunosuppressive therapy, 5-year renal and patient survival is 65% to 75%.³⁸ The likelihood of success of long-term maintenance of renal function is inversely correlated with the serum creatinine concentration when therapy begins, which indicates the importance of early diagnosis and prompt initiation of appropriate treatment. The likelihood of the patient's survival increases with early treatment of pulmonary hemorrhage and sepsis and avoidance of overimmunosuppression leading to life-threatening infections.⁴² Older age, higher serum creatinine concentration at presentation, pulmonary hemorrhage, and especially dialysis-dependent renal failure correlate with an overall poor outcome.³⁸ However, even dialysis-dependent renal failure may resolve with aggressive early therapy. Respiratory tract disease and PR3-ANCA are predictors of higher relapse rates.^{39,42} Pathologic features that correlate with renal outcome include histologically normal glomeruli, glomerular sclerosis, interstitial leukocyte infiltration, tubular necrosis, and tubular atrophy.³⁹ Glomerular filtration rate (GFR) at 18 months after diagnosis correlates with interstitial fibrosis and tubular atrophy, whereas the extent of recovery of renal function correlates with glomerular crescents and necrosis.⁴⁰ This suggests that active inflammatory lesions may be suppressed if not reversed by treatment, whereas chronic injury at the time that treatment is begun may be irreversible.

When severe GN is present, the renal prognosis is similar for patients with Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, and isolated pauci-immune crescentic GN. Renal involvement, however, is not usually present or is mild in patients with Churg-Strauss syndrome. Cardiac involvement is the most frequent cause of death in patients with Churg-Strauss syndrome but only rarely causes mortality in microscopic polyangiitis or Wegener's granulomatosis. Wegener's granulomatosis has a broad spectrum of clinical manifestations, from very localized indolent disease to fulminant multisystem disease. For example, some patients have disease limited to the upper respiratory tract or to the upper and lower respiratory tract. Such limited disease may have a more benign natural history than systemic disease with substantial renal involvement and may warrant less aggressive treatment.

Patients with MPO-ANCA have a slightly better renal outcome than do those with PR3-ANCA even though they have more renal impairment and more chronic renal pathologic changes at presentation.³⁶⁻⁴² Patients with PR3-ANCA have more extrarenal organ manifestations (especially respiratory tract disease), higher chance for relapse, and higher mortality than MPO-ANCA patients do. Irrespective of the category of ANCA disease, the best clinical predictor of renal outcome is the GFR at the time of diagnosis, and the best pathologic predictor of response to treatment is the extent of active necrosis and cellular crescents in biopsy specimens.⁴⁰

Treatment

This section focuses on patients with ANCA-associated small-vessel vasculitis affecting the kidneys. The goal should be not to overtreat mild disease and not to undertreat severe disease. GN that is severe enough to cause renal impairment is an indication for immunosuppressive treatment in patients with Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, and isolated pauci-immune crescentic GN. Patients with ANCA-associated small-vessel vasculitis who have concurrent anti-GBM disease or concurrent immune complex disease should be treated similarly to patients with ANCA disease alone.

Treatment involves three phases: induction of remission, maintenance of remission, and treatment of relapse.^{38,43}

Induction Therapy

The consensus is that corticosteroids alone are not as effective for induction therapy as are corticosteroids combined with a cytotoxic agent such as cyclophosphamide.^{38,42-49} Combined treatment with corticosteroid and cyclophosphamide induces remission in approximately 75% of patients at 3 months and 90% at 6 months. The specifics of combined induction regimens vary with respect to agents, doses, route of administration, and duration. One induction approach is to begin with 7 mg/kg/day intravenous methylprednisolone for 3 days followed by oral prednisone 1 mg/kg/day, tapering to an alternate-day regimen and discontinuing within 3 to 4 months.⁴⁴ Alternatively, the corticosteroids can be administered as 1 mg/kg/day prednisolone tapered to 0.25 mg/kg/day by 3 months.⁴⁸ The corticosteroid treatment is combined with 2 mg/kg/day oral cyclophosphamide or intravenous cyclophosphamide at 0.5 g/m² per month adjusted upward to 1 g/m² on the basis of the leukocyte count after 2 weeks with a target nadir of 3000 cells/mm³. The dose of oral cyclophosphamide can be reduced by 25 mg for patients older than 60 years.⁴⁸

The role of plasma exchange as a component of induction therapy is becoming better defined. Plasma exchange may be of benefit in two specific populations: (1) those with life-threatening pulmonary hemorrhage⁵⁰ and (2) those who have dialysis-dependent renal failure at the time of presentation.⁵¹ With respect to pulmonary hemorrhage, 20 of 20 patients treated with early plasma exchange had resolution of pulmonary bleeding compared with a 50% mortality rate in historical controls.⁵⁰ A trial by the European Vasculitis Study Group (MEPEX) evaluated the efficacy of intravenous methylprednisolone as induction therapy or plasma exchange in patients who had a serum creatinine concentration of more than 500 μmol/L.⁵¹ Results from this study suggest that plasma exchange compared with pulse methylprednisolone in this population increases the rate of recovery from renal failure. Patient survival and adverse events were similar in patients who did or did not receive plasma exchange. Plasma exchange was associated with a 24% reduced risk of progression to end-stage renal disease (ESRD) (43% to 19% at 1 year). A subsequent study is being undertaken to more fully evaluate the role of plasma exchange in ANCA-positive patients.

Maintenance Therapy

The duration of induction therapy and the intensity of maintenance therapy should be reduced as much as possible to reduce toxic side effects. This is a difficult challenge because of the tendency of the pauci-immune small-vessel vasculitides to recur. A number of approaches have been used to reduce the cyclophosphamide dose, such as giving less cyclophosphamide through intravenous rather than oral schedules,^{44,50} substituting a less toxic maintenance drug after 3 to 6 months,⁴⁸ and discontinuing therapy earlier in patients with lower risk of relapse. Intravenous cyclophosphamide regimens afford one third to one half of the total dose of cyclophosphamide given in oral regimens. A head-to-head comparison by the European Vasculitis Study Group (CYCLOPS trial) indicates that intravenous cyclophosphamide results in the same remission and relapse rates as oral cyclophosphamide does while reducing the total dose of cyclophosphamide.⁵² Another approach to reducing cyclophosphamide dose is to convert to azathioprine after 3 to 6 months of therapy.^{38,48} In the European Vasculitis Study Group CYCAZAREM trial, cyclophosphamide was replaced with 2 mg/kg/day azathioprine

after 3 to 6 months with no change in the relapse rate at the end of the study.⁴⁸ Cyclophosphamide dose also could be reduced by alternative induction therapies. In a randomized trial of cyclophosphamide versus methotrexate in patients without critical organ damage and primarily ear, nose, and throat disease, methotrexate was less effective for inducing remission in patients who developed extensive disease and pulmonary involvement and was associated with more relapses than cyclophosphamide.⁵³ A study by the French Vasculitis Study Group has examined methotrexate compared with azathioprine as maintenance therapy in patients with Wegener's granulomatosis and microscopic polyangiitis. In this study, methotrexate was as effective as azathioprine for maintenance of remission, but methotrexate did not have fewer side effects.⁵⁴ An attractive alternative is to stop induction therapy at 6 to 12 months if the patient is in full remission, especially if the patient is at lower risk of relapse.⁴²

Additional immunosuppressive agents that have been used for maintenance therapy in patients who have not responded well to more conventional treatment include anti-tumor necrosis factor α (anti-TNF α) (infliximab, etanercept), anti-CD20 (rituximab), and mycophenolate mofetil (MMF).⁵⁴⁻⁵⁸ The results are not yet conclusive; however, MMF appears to be of some value at least as an adjunct to current immunosuppressive regimens.⁵⁷ There are a number of anecdotal and early randomized trial results with use of rituximab in therapy for small-vessel vasculitis. Whereas the initial reports appear encouraging, the full results of a true randomized control trial need to become available for the place of rituximab therapy to be more fully understood. The cost of this medication precludes its use at present, other than for those individuals who are refractory to other therapy and when leukopenia and infectious complications are problematic. In this population, there is evidence that rituximab can induce partial or complete remission.⁵⁴ The Wegener's Granulomatosis Etanercept Trial (WGET) examined the use of etanercept in addition to a methotrexate-based maintenance therapy.⁵⁸ This study was marked by a very low long-term remission rate of approximately 50% and a high rate of disease flares. Six patients treated with etanercept developed solid cancers. The investigators concluded that etanercept is not effective for the maintenance of remission in patients with Wegener's granulomatosis.⁵⁸

The role of antimicrobial agents, such as trimethoprim-sulfamethoxazole, in maintenance of remission is controversial. Some studies have suggested a benefit, but others have not because of an increased likelihood of relapse.^{59,60} Trimethoprim-sulfamethoxazole may be useful adjunct therapy, especially in patients with upper respiratory tract disease, but it should not be used in the absence of immunosuppressive drugs with more proven efficacy (e.g., cyclophosphamide, azathioprine) for induction or maintenance therapy for systemic vasculitis or GN.

Relapse Therapy

Approximately one fourth to one half of patients with pauci-immune small-vessel vasculitis and GN will experience a relapse within several years. Relapses are diagnosed on the basis of solid clinical and pathologic evidence of recurrent disease, not by an increase in ANCA titer alone.^{33,34} However, an increase in ANCA titer increases the likelihood of a relapse, and there are some advocates for preemptive immunosuppressive therapy if the ANCA titer increases by at least fourfold.³⁴ We prefer to identify clear-cut clinical or pathologic evidence of relapse before increasing immunosuppressive therapy.⁴⁴

The best treatment for relapses is unsettled. Reinstitution of treatment similar to an induction regimen is used most often,

but less intensive or less toxic therapy may be adequate.^{38,44,45} A number of therapies have been used, including cyclophosphamide, rituximab, intravenous immune globulin, and MMF in combination with methotrexate or azathioprine, and combinations of these drugs must be tailored to the individual patient with recalcitrant disease.

In some individuals, long-term therapy may not be required, especially if there is a very low risk of relapse. In prospective observational studies from the Glomerular Disease Collaborative, the relative risk of relapse was increased in those individuals who had PR3-ANCA and ear, nose, and throat disease and lung disease.⁴² Patients had more than a threefold risk of relapse compared with those individuals with MPO-ANCA and without lung or ear, nose, and throat disease. In a follow-up study, this model of relapsing disease was investigated in a separate registry in France, in which PR3-ANCA in lung disease was the most important predictive marker.⁶¹ Thus, it is possible that in those who have a much smaller risk of relapse, all therapy can be stopped, provided the patient and physician pursue a monitoring course in which the risk of early relapse is detected, for example, urinary dipstick testing in the home to monitor for the recurrence of hematuria. The risk of relapse is on the order of 10% to 15% even with remission maintenance therapy.

Transplantation

There are a few reports of recurrent disease in renal transplants given to patients with ESRD caused by pauci-immune crescentic GN, but they are not numerous enough to be a contraindication to transplantation. Although the data are limited, the frequency of recurrence appears to be approximately 20%, but graft loss caused by recurrence may be less than 5% (see Chapter 104). A positive ANCA titer at the time of transplantation does not increase the risk of recurrent disease in the transplant.^{62,63} Recurrent ANCA GN in a renal transplant responds similarly to recurrent disease in native kidneys.⁶³ As with native kidney disease, an increase in ANCA titer and an active urine sediment should raise the possibility of recurrent GN, but the diagnosis requires pathologic confirmation.

POLYARTERITIS NODOSA

Polyarteritis nodosa is a systemic necrotizing arteritis that affects predominantly main visceral arteries and their intraparenchymal branches.^{1,4,5,64} There is still much confusion about the relationship between polyarteritis nodosa and microscopic polyangiitis (which also has been referred to as microscopic polyarteritis). The Chapel Hill Nomenclature System limits the diagnosis of polyarteritis nodosa to patients who have only arteritis.⁴ The presence of vasculitis in vessels other than arteries, such as capillaries, venules, or arterioles, excludes a diagnosis of polyarteritis nodosa and indicates some form of small-vessel vasculitis. Thus, GN excludes a diagnosis of polyarteritis nodosa. When polyarteritis nodosa is distinguished from microscopic polyangiitis by this approach, the two categories of vasculitis have not only different pathologic characteristics but also different clinical features and natural histories, which justifies the nosologic distinction between polyarteritis nodosa and microscopic polyangiitis.^{5,64-68}

Pathogenesis

The etiology and pathogenesis of polyarteritis nodosa are unknown. When polyarteritis nodosa is separated from micro-

scopic polyangiitis, the latter but not the former is associated with ANCA. An immune complex trigger for polyarteritis nodosa has been proposed but has not been confirmed as the major pathogenetic process. A minority of patients have hepatitis B virus infection, which has raised the possibility that the hepatitis B virus infection is producing immune complexes that are localizing in artery walls and inducing inflammation.⁶⁸ However, the evidence that hepatitis B virus infection is causing vascular immune complex deposition is stronger in certain forms of GN and small-vessel vasculitis than in polyarteritis nodosa.

Epidemiology

When it is defined by the Chapel Hill nomenclature system, polyarteritis nodosa has a prevalence of approximately 3/100,000 compared with 2.5/100,000 for microscopic polyangiitis, 2.5/100,000 for Wegener's granulomatosis, and 1/100,000 for Churg-Strauss syndrome.²⁴ This population study was carried out in an urban area in France, and the authors pointed out that this is a higher prevalence for polyarteritis nodosa compared with the ANCA-associated vasculitides than has been reported in other studies. They suggested that environmental factors may influence the prevalence of polyarteritis nodosa. Polyarteritis nodosa affects males and females equally and is found in all races. Onset is most frequent between the ages of 40 and 60 years.

Clinical Manifestations

The usual clinical presentation of polyarteritis nodosa includes nonspecific constitutional symptoms, such as fever, malaise, arthralgias, myalgias, and weight loss, as well as manifestations of arteritis.⁶⁴⁻⁶⁸ Peripheral neuropathy, typically in the form of a mononeuritis multiplex, is a common manifestation. This is caused by inflammation of small epineural arteries and is clinically indistinguishable from the peripheral neuropathy caused by other forms of vasculitis that can affect epineural arteries, such as microscopic polyangiitis, Wegener's granulomatosis, and Churg-Strauss syndrome. Gastrointestinal involvement occurs in about half of patients, usually manifested as abdominal pain and blood in the stool. Bowel infarction is uncommon and perforation is rare. Renal involvement produces infarction and hemorrhage, which are indicated by flank pain and hematuria. Rupture of an arterial aneurysm with retroperitoneal or peritoneal hemorrhage is an uncommon but potentially lethal renal complication. Approximately one third of patients develop hypertension, which rarely reaches the malignant range. Red, tender inflammatory nodules are the most common cutaneous manifestation. Infarction, ulceration, and livedo reticularis may be present.

Arterial aneurysms may be detected by angiography in patients with polyarteritis nodosa (Fig. 24.15). This is not a completely specific determination because any necrotizing arteritis that affects arteries large enough to be seen by angiography can produce this finding.

Pathology

Any artery in the kidney can be affected by polyarteritis nodosa, from the main renal artery to the interlobular arteries, although the interlobar and arcuate arteries are affected most often.¹ Nodular inflammatory lesions and aneurysms (pseudoaneurysms) can be observed grossly when medium-sized arteries are involved. Inflammation in small arteries can be observed only by microscopy.

Figure 24.15 Renal angiogram in polyarteritis nodosa. Angiogram shows patchy renal perfusion defects and aneurysms (arrows).

Figure 24.16 Necrotizing arteritis in an arcuate artery of a patient with polyarteritis nodosa. The lumen is partially occluded by thrombotic material that is continuous with the fibrinoid material that has replaced the entire wall of the artery. (Hematoxylin-eosin; original magnification $\times 50$.)

The characteristic acute lesion is segmental transmural fibrinoid necrosis of arteries, usually accompanied by infiltrating leukocytes with leukocytoclasia (Fig. 24.16).^{3,69} The earliest lesions have numerous neutrophils, and later lesions have predominantly mononuclear leukocytes. Acute lesions may be complicated by thrombosis or hemorrhage. Older lesions develop fibrosis and endarterial remodeling. The aneurysms of necrotizing arteritis are not true aneurysms but rather are inflammatory pseudoaneurysms. That is, the walls of the arteries are not dilated but rather have been eaten away by the necrotizing inflammation, which then erodes into the surrounding perivascular tissue to create an enlarged lumen at the site of inflammation. This explains the propensity for such lesions to induce thrombosis or to undergo rupture.

The necrotizing arteritis of polyarteritis nodosa cannot be distinguished by light microscopy from arteritis caused by other

necrotizing vasculitides affecting arteries.^{1,2} For example, necrotizing arteritis in a skeletal muscle biopsy specimen or a peripheral nerve biopsy specimen is histologically identical whether it is caused by polyarteritis nodosa, microscopic polyangiitis, Wegener's granulomatosis, or Churg-Strauss syndrome. For these vasculitides to be distinguished, additional clinical and serologic information is required.

Differential Diagnosis

Polyarteritis nodosa must be distinguished from other forms of vasculitis, especially other forms of necrotizing vasculitis that can affect arteries, such as microscopic polyangiitis. Lhote and Guillevin⁶⁷ have identified clinical features that assist in the differential diagnosis (Fig. 24.17).

A positive ANCA test result supports the presence of one of the ANCA-associated small-vessel vasculitides rather than polyarteritis nodosa. The presence of GN indicates some form of small-vessel vasculitis rather than polyarteritis nodosa. Vasculitic pulmonary disease is rare in polyarteritis nodosa but is frequent in microscopic polyangiitis, Wegener's granulomatosis, and Churg-Strauss syndrome. Peripheral neuropathy or muscle tenderness with arteritis in epineural or skeletal muscle arteries is not a useful differentiating feature because it is frequent in polyarteritis nodosa as well as in the ANCA-associated small-vessel vasculitides. Kawasaki disease causes necrotizing arteritis but is distinguished from polyarteritis nodosa by the presence of the mucocutaneous lymph node syndrome.

Natural History

The natural history of polyarteritis nodosa is difficult to determine because most of the early studies of outcome grouped polyarteritis nodosa together with microscopic polyangiitis. Polyarteritis nodosa with multisystem involvement has a very poor prognosis without therapy. Polyarteritis nodosa usually is treated with corticosteroids and cytotoxic drugs, such as cyclophosphamide.⁶⁶ The 10-year survival rate with appropriate treatment is approximately 80%. Approximately 15% of patients who enter remission develop a relapse, which is much less frequent than with microscopic polyangiitis. Relapse is more likely if treatment is delayed.

Treatment

Polyarteritis nodosa in patients with no evidence of hepatitis B virus infection is treated with corticosteroids and cytotoxic drugs, usually cyclophosphamide.^{45,64-67} The regimens vary and include treatment approaches similar to those described earlier for microscopic polyangiitis and Wegener's granulomatosis. However, in patients with no risk factors for poor outcome (such as age older than 50 years, cardiac involvement, gut involvement, or renal involvement), corticosteroids alone may be adequate and are less toxic therapy than corticosteroids combined with cytotoxic agents.

Aggressive immunosuppressive therapy without initial antiviral therapy is contraindicated in patients with hepatitis B virus-associated polyarteritis nodosa because of potential adverse effects on the outcome of the hepatitis B virus infection. Short-term corticosteroid treatment combined with antiviral agents and possibly plasma exchange should precede more extensive immunosuppression in such patients.^{65,68} The European League Against Rheumatism (EULAR) recommends initial treatment

Clinical Differences Between Polyarteritis Nodosa and Microscopic Polyangiitis

Clinical Feature	Polyarteritis Nodosa	Microscopic Polyangiitis
Microaneurysms by angiography	Yes	No (?rare)
Rapidly progressive nephritis	No	Yes (very common)
Pulmonary hemorrhage	No	Yes
Renovascular hypertension	Yes (10%–33%)	No
Peripheral neuropathy	Yes (50%–80%)	Yes (10%–20%)
Positive hepatitis B serology	Uncommon	No
Positive antineutrophil cytoplasmic antibody	Rare	Frequent
Relapses	Rare	Frequent

Figure 24.17 Clinical differences between polyarteritis nodosa and microscopic polyangiitis. (Modified from reference 26.)

with high-dose corticosteroids tapered during 2 weeks followed by antiviral treatment.⁴⁵ The addition of plasma exchange may increase the likelihood of remission.

KAWASAKI DISEASE

Definition

Kawasaki disease is an acute febrile illness that usually occurs in young children, often younger than 1 year, and is characterized by the mucocutaneous lymph node (MCLN) syndrome (see later discussion).^{4,70–72} Necrotizing arteritis is a complication of Kawasaki disease that is present in some but not all patients. Clinically significant renal involvement is very rare; therefore, Kawasaki disease is rarely encountered by nephrologists.

Pathogenesis

The occasional occurrence of Kawasaki disease as an endemic or epidemic disease suggests that the cause may be an infectious agent or an environmental toxin. Both cell-mediated and antibody-mediated mechanisms have been incriminated, including a possible role for antiendothelial antibodies.⁷² At the current time, the etiology and pathogenesis of Kawasaki disease are unproven.

Epidemiology

Kawasaki disease usually occurs in children younger than 5 years and has a peak incidence in the first year of life. It was first described in Japan, but it occurs worldwide. The disease is more common in Asians and Polynesians than in Caucasians and blacks. In Japan, the incidence is 50/100,000 children younger than 5 years, with 50% of the children younger than 2 years.⁷³ Kawasaki disease occasionally occurs in an endemic or epidemic pattern but usually is sporadic.

Clinical Manifestations

MCLV syndrome is the characteristic clinical manifestation of Kawasaki disease.^{4,72} This includes fever (temperature of usually 38°C to 40°C), mucosal inflammation, swollen red tongue (strawberry tongue), polymorphous erythematous rash, indurative edema of the extremities, erythema of palms and soles,

Figure 24.18 Kawasaki disease arteritis affecting a renal interlobar artery in a young child. The artery wall is intact on the far left. The remainder of the wall has extensive edema, infiltration by mononuclear leukocytes, and a band of fuchsinophilic (red) fibrinoid material roughly at the junction between the inflamed intima and muscularis. (Masson trichrome; original magnification ×25.)

desquamation from the tips of digits, conjunctival injection, and enlarged lymph nodes.

The frequency of active arteritic lesions peaks during the first week of the illness and is markedly reduced after 1 month. Arteritis most often is manifested as cardiac disease. Thrombosis of inflamed coronary arteries in patients with Kawasaki disease is the most common cause of childhood myocardial infarction. Clinically significant renal disease is uncommon. This is somewhat surprising because autopsy reveals arteritis in renal vessels in up to three fourths of patients.⁷⁰

Pathology

The arteritis of Kawasaki disease involves small and medium-sized arteries. The acute histologic lesion is necrotizing inflammation with less fibrinoid necrosis and more edema than is usually observed with polyarteritis nodosa (Fig. 24.18).⁶⁹ Aneurysm (pseudoaneurysm) formation and thrombosis may occur.

The most frequent site of arteritis is the coronary arteries, followed by the renal arteries.⁷⁰ Arteritis most often affects interlobar arteries, occasionally arcuate arteries, and only rarely interlobular arteries.

Differential Diagnosis

Kawasaki disease has sometimes been misdiagnosed as childhood polyarteritis nodosa. The differentiation of Kawasaki disease from polyarteritis nodosa is very important because corticosteroid treatment may increase the risk of coronary artery aneurysms in Kawasaki disease. Arteritis in a child younger than 5 years should always raise the possibility of Kawasaki disease. The presence or absence of the MCLN syndrome is the basis for distinguishing between Kawasaki disease and other forms of arteritis.⁴

Natural History

Kawasaki disease usually is self-limited with an uneventful recovery if it is treated promptly with intravenous gamma globulins.^{71,72} Recurrence is rare. Only about 1% of patients develop severe arteritic complications, usually affecting the coronary arteries.

Treatment

Aspirin and intravenous gamma globulin are the standard therapy for Kawasaki disease.^{71,72} Corticosteroid treatment may increase the risk of adverse coronary artery complications, although the data supporting this are limited.

TAKAYASU ARTERITIS AND GIANT CELL ARTERITIS

Takayasu arteritis and giant cell arteritis affect the aorta and its major branches.^{4,69,74} Giant cell arteritis has a predilection for the extracranial branches of the carotid artery but can affect arteries in almost any organ. Takayasu arteritis has a predilection for major arteries supplying the extremities. Both diseases cause chronic vascular inflammation, often with a granulomatous appearance that may include multinucleated giant cells. Giant cell arteritis, but not Takayasu arteritis, is associated with polymyalgia rheumatica.

Pathogenesis

The etiology and pathogenesis of giant cell arteritis and Takayasu arteritis are unknown. Because of the histologic changes and the nature of the infiltrating leukocytes, cell-mediated immune mechanisms are incriminated. The inciting antigen or autoantigen has not been identified.

Epidemiology

Takayasu arteritis is seen most frequently in Asia. Giant cell arteritis is most frequent in individuals of northern European ancestry. Takayasu arteritis has a female-to-male ratio of approximately 9:1, and giant cell arteritis has a female-to-male ratio of 4:1. Takayasu arteritis usually is diagnosed in those between the ages of 10 and 20 years and is very rare after 50 years of age. Giant cell arteritis is very rare before the age of 50 years.

Clinical Manifestations

In addition to nonspecific constitutional symptoms, such as fever, arthralgias, and weight loss, the major clinical manifestations of

Takayasu arteritis and giant cell arteritis are caused by arterial narrowing and resultant ischemia.⁷⁴

The major clinical manifestations of Takayasu arteritis are reduced pulses (95% of patients), vascular bruits, claudication, and renovascular hypertension. Renovascular hypertension is a major cause of morbidity and mortality and results from renal ischemia caused by renal artery stenosis or aortic coarctation.^{74,75} Reduced aortic elasticity and impairment of carotid artery baroreceptors also may play a role in some patients. EULAR recommends thorough imaging assessment of the entire major arterial tree when a diagnosis of Takayasu arteritis is suspected.⁷⁶

Headache is the most common presenting symptom in patients with giant cell arteritis. Temporal artery tenderness, nodularity, or decreased pulsation is present in about half of patients. Additional common symptoms include blindness, deafness, jaw claudication, tongue dysfunction, extremity claudication, and reduced pulses. More than half of patients with giant cell arteritis have polymyalgia rheumatica, which is characterized by stiffness and aching in the neck and the proximal muscles of the shoulders and hips. Clinically significant renal disease is much rarer in giant cell arteritis than in Takayasu arteritis. There are case reports of necrotizing and crescentic GN associated with giant cell arteritis, but these may represent examples of Wegener's granulomatosis or microscopic polyangiitis with temporal artery involvement.

Pathology

The aortitis and arteritis of Takayasu arteritis and giant cell arteritis cannot be confidently distinguished from each other by pathologic examination.⁶⁹ Both are characterized in the active phase by inflammation with a predominance of mononuclear leukocytes, often with scattered multinucleated giant cells (Fig. 24.19). The chronic phase is characterized by progressive fibrosis that may cause severe narrowing of vessels, with resultant ischemia. Major renal arteries are often found to be involved at autopsy in both Takayasu arteritis and giant cell arteritis patients. However, clinically significant renal disease is relatively common in Takayasu arteritis but rare in giant cell arteritis. A glomerular lesion characterized by nodular mesangial matrix expansion and mesangiolysis may occasionally be a component of Takayasu arteritis.⁷⁷

Figure 24.19 Severe giant cell arteritis affecting a main renal artery. This caused marked renal atrophy and renovascular hypertension. (Hematoxylin-eosin; original magnification ×50.)

Differential Diagnosis

There is a great deal of overlap between the clinical manifestations and pathologic features of Takayasu arteritis and giant cell arteritis. The age of the patient and the presence or absence of polymyalgia rheumatica are the best features for discriminating between these two vasculitides.

Giant cell arteritis also has been called temporal arteritis. This is a misleading designation because not all patients have temporal artery involvement, and patients with other types of vasculitis, such as polyarteritis nodosa, Wegener's granulomatosis, and microscopic polyangiitis, can have involvement of the temporal arteries. Some of the reported examples of necrotizing GN associated with temporal arteritis probably represent Wegener's granulomatosis or microscopic polyangiitis with temporal artery involvement.

Treatment

Corticosteroids are the usual treatment of giant cell arteritis and Takayasu arteritis.⁷⁶ EULAR recommends initial daily therapy with 1 mg/kg prednisolone for 1 month followed by tapering during several months.⁷⁶ More prolonged treatment may be dictated by persistent disease activity. Cytotoxic agents such as cyclophosphamide may be required in patients with recalcitrant disease. Patients with giant cell arteritis also should receive low-dose aspirin to protect against thrombotic vascular events.⁷⁶

Management of renal disease is not an issue with typical giant cell arteritis, although rare patients have ischemic renal manifestations. Renovascular hypertension is the major renal problem caused by Takayasu arteritis.^{74,75} When bilateral renal artery involvement occurs, angiotensin-converting enzyme (ACE) inhibitors may precipitate renal failure in patients with Takayasu arteritis.⁷⁸ When medical management fails, the renovascular hypertension in patients with Takayasu arteritis may be controlled by bypass surgery or angioplasty.⁷⁵ Reconstructive vascular surgery should be performed during a quiescent phase of the disease.⁷⁶ The management of renovascular hypertension is covered in Chapter 37.

Lupus Nephritis

Gerald B. Appel, David Jayne

DEFINITION

Lupus nephritis (LN) is a common and serious feature of systemic lupus erythematosus (SLE).¹⁻⁴ SLE itself is defined by a combination of clinical and laboratory features. The American College of Rheumatology (ACR) criteria (Fig. 25.1) for the diagnosis of SLE have been widely used in both epidemiologic and treatment studies. However, many patients with “lupus-like” conditions or others who have as yet met fewer than four ACR criteria should still be recognized as requiring therapy.

EPIDEMIOLOGY

The incidence and prevalence of lupus and LN are influenced by age, gender, ethnicity, geographic region, diagnostic criteria employed, and method of ascertainment.⁵ The peak incidence of lupus is 15 to 45 years, with females outnumbering males by 10:1. This gender predominance is less pronounced in children and older individuals. Among lupus patients, LN affects both genders equally and is more severe in children and men and less so in older adults. Both lupus and LN are three to four times more common in African Americans, Afro-Caribbeans, Asians, and Hispanic Americans than in Caucasians. Additional risk factors for renal disease include younger age, lower socioeconomic status, more ACR criteria for SLE, longer duration of disease, family history of SLE, and hypertension.

ETIOLOGY AND PATHOGENESIS

Genetics, Environment, and Animal Models

Multiple genes predispose to lupus.^{3,5,6} This is supported by the clustering in families, the racial differences in susceptibility, the concordance of SLE in more than 25% of identical twins but in only 5% of fraternal twins, and the frequency of positive autoantibodies and other autoimmune disorders in family members of SLE patients. Homozygous deficiency of certain complement components (C1q, C2, C4) carries a high risk for development of SLE; this is also true for certain FcγRIII receptor polymorphisms. Genome-wide association studies have identified 17 loci associated with an increased risk of SLE that involve genes associated with B-cell signaling, Toll-like receptors, and neutrophil function.⁷ Environmental factors also play a role in the onset of SLE and LN. Sun or ultraviolet light exposure and “sunburn” can precipitate and exacerbate SLE and LN.^{3,5} Hormonal factors are evidenced by the strong female predisposition, the exacerbations during or shortly after pregnancy, and the role of hormonal treatment and ablation in animal models of LN. Whereas

exposure to certain medications can produce SLE or a lupus-like syndrome, renal disease is infrequent in these patients. Conclusive evidence for a viral pathogenesis of SLE or LN has yet to be produced. Spontaneous and inducible models of SLE in mice include the NZB B/W F1 hybrid, the BXSB, and the MRL/lpr models.^{3,6} Some of these models have defective apoptosis that may lead to defective clonal deletion and B-cell proliferation. SLE can be induced in animal models by injection of autoantibodies against DNA or phospholipids and by injection of peptides derived from Smith antigen.

Autoimmunity in Systemic Lupus Erythematosus

SLE patients typically develop a wide range of autoantibodies.⁶⁻⁹ The disease process starts with a breakdown in self tolerance and autoantibody production. Subsequently, deposition of immune complexes and the inflammatory responses in various organs dictate the nature and extent of disease.³ Many autoantibodies are directed against nucleic acids and proteins concerned with transcriptional and translational machinery, such as nucleosomes (DNA-histone), chromatin antigens, and small nuclear and cytoplasmic ribonuclear proteins. Polyclonal hyperactivity of B cells along with defective autoregulation of T cells is thought to underlie autoantibody production.⁶⁻⁹ A number of mechanisms may contribute to this condition, including failure to remove or to silence autoreactive B and T cells, abnormal exposure to or presentation of self antigens, T-cell hyperactivity, increased B cell-stimulating cytokines, and B-cell hyperactivity.⁶ The failure of apoptotic mechanisms to delete or to silence autoreactive cells (tolerance) may allow clonal expansion of such cells later in life, leading to autoreactive cells and autoantibody production. Abnormal exposure to self antigen may occur through nuclear autoantigens clustering on the blebs of apoptotic cells, which may be associated with germline mutations that lead to clonal expansion of autoreactive cells. Likewise, “antigen mimicry” may occur if exposure to viral or bacterial peptides containing sequences similar to native antigens leads to a similar induction of autoantibody-producing cell lines. The nature of antigen presentation may also be important, with certain nuclear antigens capable of triggering an immunogenic response through interactions with a variety of intracellular Toll-like receptors. In SLE, there is evidence that T-cell hyperactivity and failure of T-cell tolerance may allow autoreactive T cells to drive B-cell proliferations and the production of autoantibodies. Finally, proliferation of autoreactive B cells may occur through a variety of disturbances of positive and negative regulatory mechanisms (e.g., through stimulation by superantigens) in addition to the mechanisms mentioned. The end result is the loss of tolerance and production of a wide array of autoantibodies.⁶⁻⁹

American College of Rheumatology Criteria for the Diagnosis of Lupus	
The presence of four or more of the following criteria gives 96% sensitivity and specificity for the diagnosis of lupus	
1. Malar rash	
2. Discoid rash	
3. Photosensitivity	
4. Oral ulcers	
5. Nonerosive arthritis	
6. Pleuropericarditis	
7. Renal disease (proteinuria and/or cellular casts)	
8. Neurologic disorder (seizures or psychosis in the absence of precipitating circumstances)	
9. Hematologic disorder (hemolytic anemia, leukopenia/lymphopenia, thrombocytopenia)	
10. Positive LE cell preparation, raised anti-DNA antibody, anti-Sm present, false-positive antitreponemal test)	
11. Positive fluorescent antinuclear antibody test	

Figure 25.1 American College of Rheumatology criteria for the diagnosis of lupus.

Pathogenesis of Lupus Nephritis

In SLE, some autoantibodies, such as those causing autoimmune hemolytic anemia, are directly pathogenic.⁷ Other autoantibodies combine with antigen to produce immune complexes that if not adequately cleared may deposit in various organs, inciting inflammatory responses.^{3,4} Complement components aid apoptotic clearance and removal of immune complexes, but they are also activated by and incorporated into the immune complexes and contribute to the inflammatory cascade. A hallmark of glomerular involvement in LN is the deposition of circulating immune complexes and the *in situ* formation of others. Although patients with LN have autoantibodies against double-stranded DNA (dsDNA), Sm antigen, C1q, and a variety of other antigens, the exact role of each in the immune complex formation seen in glomerular disease remains unclear. In proliferative LN, DNA and high-affinity complement-fixing antibodies are found. Immune complex deposition may also be facilitated by cationic histones that bind to the glomerular basement membrane. In general, mesangial and subendothelial immune deposits are derived from deposition of circulating immune complexes, whereas subepithelial complexes are often formed *in situ*. However, whether deposition of circulating complexes or *in situ* formation is the predominant pathogenic pathway in a given patient is not always clear. The localization of immune complexes within the glomerulus is influenced by size, charge, and avidity as well as by the clearing ability of the mesangium and local hemodynamics.^{3,4} The localization of immune complexes in the glomerulus leads to complement activation and complement-mediated damage, activation of procoagulant factors, leukocyte infiltration with release of proteolytic enzymes, and activation of cytokines associated with cellular proliferation and matrix formation. Intraglomerular hypertension and activation of coagulation cascades may contribute to the glomerular injury especially in patients with antiphospholipid antibodies (APA). Additional components of extraglomerular renal damage in LN include vascular damage ranging from simple localization of immune complexes to rare necrotizing vasculitis and tubulointerstitial disease.

Renal Manifestations in Patients with Lupus	
Manifestation	Prevalance
Proteinuria	100%
• Nephrotic syndrome	45–65%
Hematuria	
• Microhematuria	80%
• Red cell casts	10%
• Macrohematuria	1–2%
Cellular casts	30%
Reduced renal function	40–80%
• RPGN	10–20%
• AKI	1–2%
Hypertension	15–50%
Hyperkalemia	15%
Tubular abnormalities (usually asymptomatic)	60–80%

Figure 25.2 Renal manifestations in patients with lupus. RPGN, rapidly progressive glomerulonephritis; AKI, acute kidney injury.

CLINICAL MANIFESTATIONS

SLE can affect virtually any organ of the body. The disease course of SLE is characterized by episodes of illness (flares) followed by episodes of relative quiescence (remissions). A number of reliable and reproducible scoring systems have been devised to follow the activity of an individual patient with SLE. These include the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), the British Isles Lupus Assessment Group (BILAG), and the Systemic Lupus Activity Measure (SLAM).

Renal Manifestations

From 30% to 50% of SLE patients will have clinically evident renal disease at presentation (Fig. 25.2).^{1–4} During follow-up, renal involvement will occur in 60% of young adults and a greater percentage of young children. Renal involvement is manifested by proteinuria, active urinary sediment with microhematuria, dysmorphic erythrocytes and erythrocyte casts, and hypertension. In many cases with major renal involvement, the nephritic syndrome develops in association with proliferative glomerulonephritis (GN) and a decline in glomerular filtration rate (GFR). The clinical findings correlate well with histologic glomerular findings (see later discussion). Infrequently, renal disease in SLE patients presents with tubular disorders such as renal tubular acidosis with hypokalemia (type 1 RTA) or hyperkalemia (type 4 RTA) (see Chapter 12), thrombotic disorders associated with a secondary antiphospholipid syndrome (see Chapter 27), and fibrillary GN (see Chapter 26).

Extrarenal Manifestations

Patients with active SLE often present with nonspecific complaints of malaise, low-grade fever, poor appetite, and weight loss.¹⁰ Other common features include patchy alopecia; oral or nasal ulcerations; arthralgias and nondeforming arthritis; and a variety of dermal findings, including photosensitivity, Raynaud's phenomenon, and the classic "butterfly" facial rash. Livedo reticularis is seen in up to 15% of cases and may be associated with

miscarriages, thrombocytopenia, and the presence of APA.¹¹⁻¹⁴ Neuropsychiatric involvement presents with headache, nerve palsies, frank coma, and psychoses. Serositis, in the form of pleuritis or pericarditis, affects up to 40% of patients. Pulmonary hypertension can develop silently as a result of multiple pulmonary emboli or intravascular coagulation in association with APA or be caused by nonthrombotic pulmonary arterial disease. Libman-Sacks endocarditis and the far more common mitral valve prolapse can be detected either with clinical findings or by echocardiography. Splenomegaly and lymphadenopathy are present in about one fourth of patients. Hematologic abnormalities in SLE include anemia due to impaired erythropoiesis, autoimmune hemolysis, and bleeding. Thrombocytopenia and leukopenia may be part of the disease process or be due to complications of therapy. Thrombotic events should prompt a search for APA and other procoagulant abnormalities.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Whereas the diagnosis of lupus may be obvious in a young female patient in the presence of classic manifestations and serologic markers, less typical presentations can result in multiple physician consultations and diagnostic delay.¹⁴ This is due in part to the varied features of the disease, as the signs and symptoms in SLE evolve over time. Some patients, especially those with membranous LN, may present with renal disease as their initial manifestation without other systemic features. The presence of four or more ACR criteria (see Fig. 25.1) carries a 96% sensitivity and specificity for lupus. However, the ACR diagnostic criteria were developed for clinical studies and do not always prove useful in an individual patient. Other diseases mimicking SLE include fibromyalgia, Sjögren's syndrome, hematologic diseases such as thrombotic microangiopathies, and primary antiphospholipid syndrome (see Chapters 27 and 28).

Other autoimmune rheumatologic disorders, such as dermatomyositis and systemic sclerosis, can be confused with SLE. However, SLE may also present with overlapping features of other multisystem or organ-limited autoimmune syndromes. Nephritis has been reported in patients with mixed connective tissue disease when it is associated with the presence of anti-Ro and anti-La antibodies and the absence of anti-dsDNA antibodies. Rheumatoid arthritis can be associated with mesangial proliferative glomerulonephritis or renal disease due to AA amyloidosis. Some older lupus patients will present with joint deformities typical of rheumatoid arthritis.

A number of other common forms of glomerulonephritis must be distinguished from LN. Although Henoch-Schönlein purpura may present with a purpuric rash, systemic symptoms, arthritis, abdominal pain, and nephritis, the immune glomerular deposits show dominant or codominant IgA deposition. In LN, most active proliferative biopsy specimens will show a predominance of IgG and the presence of C1q and often "full house" staining with IgG, IgA, IgM, C3, and C1q present on biopsy. Pauci-immune rapidly progressive glomerulonephritis (RPGN) with antineutrophil cytoplasmic antibody (ANCA) positivity may be confused with lupus until the serologic or renal biopsy results are obtained (see Chapter 24). Patients who are seropositive for both ANCA and antinuclear antibody (ANA) or anti-dsDNA and who do not have immune deposits on renal biopsy should be treated like other pauci-immune GN patients. ANCA positivity by itself has no significance in a proven SLE patient, and false-positive MPO-ANCA assays may be seen in association with high binding levels of anti-dsDNA. Bacterial endocarditis and

cryoglobulinemia (see Chapter 21) can also mimic lupus, especially because the serum complement levels may be low.

Immunologic Tests in Lupus

Because autoantibody production is a hallmark of SLE, a firm diagnosis of LN should not be made without the presence of some serum ANA.⁷ ANA, being found in more than 90% of untreated patients, are a highly sensitive screen for SLE patients; however, they are nonspecific and are found in other rheumatologic and nonrheumatologic diseases. Some lupus-like patients with negative ANA test results will be found to have APA.¹¹⁻¹³ The presence of various patterns of ANA (diffuse, speckled) is not reliable in distinguishing lupus from similar rheumatologic diseases. Autoantibodies against dsDNA are far more specific, being present in about three fourths of untreated lupus patients, but they are a less sensitive marker. Whereas high titers of anti-dsDNA antibodies correlate with the presence of SLE and are often used to follow the course of LN, antibodies to single-stranded DNA (ssDNA) are found in many rheumatologic conditions and do not correlate with the course of LN. A variety of tests for anti-dsDNA antibodies are available, including the Farr radioimmunoassay, an immunofluorescent test directed against the DNA of the kinetoplast of *Critidia luciliae*, and an enzyme-linked immunosorbent assay (ELISA). The ELISA is the most commonly used assay. Sm antibodies are strongly associated with the diagnosis of lupus and the presence of nephritis but are present in only about 25% to 30% of patients. Antibodies to C1q (anti-C1q) have been more closely associated with the activity of LN than anti-dsDNA antibodies and may have a prognostic role in the follow-up of patients with LN.¹⁵

Serum levels of total hemolytic complement and complement components C3 and C4 are often depressed in untreated lupus patients and especially those with LN. Either C3 and C4 are both depressed or the C4 is preferentially depressed in lupus patients, reflecting preferential activation of the classical complement pathway. In patients with postinfectious glomerulonephritis and idiopathic membranoproliferative glomerulonephritis, C3 is often preferentially depressed (see Chapter 21). Alternatively, low C4 with normal C3 may reflect genetic C4 deficiency in lupus patients (see earlier discussion).

One third to one half of lupus patients will have APA.¹¹⁻¹³ The misnomer "lupus anticoagulant" is based on the presence of APA, which prolong phospholipid-dependent coagulation studies *in vitro* (activated partial thromboplastin time [APTT] and kaolin clotting time [KCT]) but *in vivo* are associated with thrombosis. The prolonged APTT and KCT are not corrected by mixing with normal plasma. The exact mechanisms for the thrombotic tendency remain unclear but may include abnormal endothelial function, enhanced platelet aggregation, reduced production of prostacyclin and other endothelial anticoagulant factors, and activation of plasminogen.^{11,12} APA have been associated with a multitude of primarily thrombotic events (see Chapter 27). APA are measured either as autoantibodies to cardiolipin or to β_2 -glycoprotein 1 (both may be of IgG or IgM isotype) or as a transferable inhibitor of coagulation (the lupus anticoagulant), best assessed by prolongation of the dilute Russell's viper venom clotting time.

PATHOLOGY

Although LN may affect all structures of the kidney, glomerular involvement has been the best studied component, and it has

been well correlated with the presentation, course, and treatment of the disease.¹⁻⁴ Adjacent glomeruli may show different degrees of involvement, and glomerular lesions may transform over time. For many years, the World Health Organization (WHO) classification of LN was used (Fig. 25.3). The 2004 modifications in the current International Society of Nephrology (ISN)/Renal Pathology Society (RPS) classification refine and clarify some of the deficiencies of the WHO classification (see Fig. 25.3).¹⁶ As in the WHO classification, the ISN classification is based on light microscopy (LM), immunofluorescence (IF), and electron microscopy (EM) findings. Interobserver reproducibility and the predictive value have improved with the ISN/RPS system.^{17,18}

ISN Classification of Lupus Nephritis

ISN class I (Fig. 25.4) denotes normal glomeruli by LM but with mesangial immune deposits. Class II (Fig. 25.5), mesangial proliferative LN, is defined as pure mesangial hypercellularity (more than three mesangial cells in areas away from the vascular pole in 3- μ m-thick histologic sections) by LM with mesangial immune deposits. Class III (Fig. 25.6), focal LN, is defined as focal segmental or global endocapillary or extracapillary glomerulonephritis affecting less than 50% of the total glomeruli sampled. Class IV (Fig. 25.7), diffuse LN, has diffuse segmental or global endocapillary or extracapillary GN affecting 50% or more of glomeruli. Both class III and class IV have subendothelial immune deposits. Class IV is subdivided into diffuse segmental (IV-S) proliferation (i.e., >50% of affected glomeruli have segmental lesions) and diffuse global (IV-G) proliferation (i.e., >50% of affected glomeruli have global lesions). Both class III and class IV may have active (proliferative), inactive (sclerosing), or combined active and inactive lesions subclassified as A, C, and A/C, respectively. ISN class V (Fig. 25.8), membranous LN, is defined by subepithelial immune deposits. The membranous alterations may be present alone or on a background of mesangial hypercellularity and mesangial immune deposits. Patients with additional true focal or diffuse proliferative lesions and subendothelial immune complex deposits are no longer classified as Vc or Vd, as in the older WHO classification, but rather as V + III and V + IV under the ISN classification (see Fig. 25.3). ISN class VI, advanced sclerosing LN, is defined by global glomerular sclerosis affecting 90% or more of glomeruli.

On IF, IgG is almost always the dominant immunoglobulin, and early complement components such as C4 and especially C1q are usually present along with C3. The presence of all three immunoglobulins, IgG, IgA, and IgM, along with the two complement components, C1q and C3, is known as full house staining. It is highly suggestive of LN, as is strong C1q staining. Fibrin is often present in the glomerular tuft and especially in crescents.

By EM, the distribution of immune deposits corresponds to that of IF. Some electron-dense deposits have an organized substructure known as fingerprinting, corresponding to the presence of curvilinear microtubular or fibrillar structures composed of bands ranging from 10 to 15 nm in diameter. Tubuloreticular inclusions, 24 nm interanastomosing tubular structures located in the dilated cisternae of endoplasmic reticulum of renal endothelial cells, are often found in biopsy specimens of patients with LN.

Tubulointerstitial and Vascular Disease

Although LN classification is based on the degree of glomerular involvement, histologic and clinical involvement of other renal

Comparison of the WHO Classification (1995) of Lupus Nephritis with the ISN/RPS Classification (2004)			
WHO, 1995		ISN/RPS, 2004	
Class	Definition	Class	Definition
I	Normal glomeruli (by LM, IF, EM)	I	Minimal mesangial LN Normal glomeruli by LM, but mesangial immune deposits by IF
II	Purely mesangial disease IIa: Normocellular mesangium by LM but mesangial deposits by IF and/or EM IIb: Mesangial hypercellularity with mesangial deposits by IF and/or EM	II	Mesangial proliferative LN Mesangial hypercellularity with mesangial immune deposits
III	Focal segmental proliferative glomerulonephritis (<50%)	III	Focal LN III (A): Purely active lesions: focal proliferative LN III (A/C): Active and chronic lesions: focal proliferative and sclerosing LN III (C): Chronic inactive lesions with glomerular scars: focal sclerosing LN
IV	Diffuse proliferative glomerulonephritis ($\geq 50\%$)	IV	Diffuse LN IV-S (A) or IV-G (A): Purely active lesions: diffuse segmental (S) or global (G) proliferative LN IV-S (A/C) or IV-G (A/C): Active and chronic lesions: diffuse segmental or global proliferative and sclerosing LN IV-S (C) or IV-G (C): Inactive with glomerular scars: diffuse segmental or global sclerosing LN
V	Membranous glomerulonephritis Va: Pure membranous Vb: Associated mild mesangial proliferation Vc: Associated focal proliferative disease Vd: Associated diffuse proliferative disease	V	Membranous LN
		VI	Advanced sclerosing LN $\geq 90\%$ of glomeruli globally sclerosed without residual activity

Figure 25.3 Comparison of the WHO classification (1995) of lupus nephritis (LN) with the ISN/RPS classification (2004). In the ISN/RPS classification, the distribution of hypercellularity is assessed as mesangial, endocapillary, or extracapillary (crescentic) and as focal (with <50% glomerular involvement) versus diffuse (with $\geq 50\%$ glomeruli affected). The distribution of immune deposits by immunofluorescence (IF) and electron microscopy (EM) is judged as mesangial, subepithelial, or subendothelial. LM, light microscopy.

Figure 25.4 ISN/RPS class I: minimal mesangial lupus nephritis. Light microscopy is normal, but immunoperoxidase shows C1q localization (associated with IgG and C3) throughout the mesangial area.

Figure 25.5 ISN/RPS class II: lupus nephritis (mesangial disease). **A**, Mesangial expansion but little increase in tuft cellularity, and the peripheral capillary walls are normal. (Silver methenamine stain.) **B**, Extensive mesangial IgG deposits shown by immunoperoxidase; the aggregates are just beginning to invade peripheral capillary walls.

compartments is not rare in lupus patients.^{3,4,19,20} In about 50% of patients with nephritis, predominantly those with proliferative glomerular lesions, immune aggregates are found along the tubular basement membranes. Interstitial infiltrates mainly of CD4⁺ and CD8⁺ T lymphocytes and monocytes are commonly found. In active disease, infiltration and invasion of the tubules

Figure 25.6 ISN/RPS class III: focal proliferative lupus nephritis. **A**, Low power showing focal and segmental proliferative lesion—active (class III A) with less than 50% of glomeruli affected. (Hematoxylin-eosin.) **B**, An area of focal necrosis containing cellular debris, karyorrhexis (arrow), is surrounded by an area of cellular proliferation. (Silver methenamine/hematoxylin-eosin.) **C**, A major focal and segmental proliferative lesion affecting almost half of the glomerular capillary tuft. (Hematoxylin/lissamine green.)

(tubulitis) is found (Fig. 25.9); in chronic disease, the interstitium is expanded by fibrosis and sparser infiltrates. Interstitial inflammation has been correlated with renal dysfunction and hypertension, whereas immune deposition along the tubular basement membranes correlates better with the presence of high anti-dsDNA and depressed serum complement levels. Infrequently, tubulointerstitial nephritis is seen in the absence of glomerular disease and may produce acute renal failure or renal tubular acidosis.

A number of vascular lesions may be seen in lupus patients (Fig. 25.10).²⁰ True vasculitis is extremely rare. More commonly, there are vascular immune deposits seen by IF or EM, or a fibrinoid noninflammatory necrotizing lesion of the vessels in patients

Figure 25.7 ISN/RPS class IV: lupus nephritis. **A**, Active diffuse proliferative lupus nephritis. **B**, By immunoperoxidase staining, there are dense irregular aggregates of IgG along the peripheral capillary walls. **C**, Electron microscopy reveals the immune aggregates as electron-dense deposits (arrows) predominantly in the subendothelial location.

Figure 25.8 ISN/RPS class V: membranous lupus. **A**, A thick (~0.5 mm) araldite-embedded section stained with toluidine blue showing not only the extramembranous material in dark blue (arrow) but also the presence of mesangial deposits, which are common in lupus membranous nephropathy. **B**, A silver methenamine–stained section showing some double contouring of the silver-positive basement membrane (arrow) and subendothelium-deposited material as well as the characteristic silver-positive spikes of basement membrane–like material. **C**, An electron microphotograph showing the predominantly subepithelial electron-dense deposits (D) separated by protrusions of basement membrane material (spikes, S). BM, basement membrane; US, urinary space.

Figure 25.9 Interstitial lupus nephritis. **A**, Interstitial infiltrate invading and destroying tubules (tubulitis). The tubular basement membrane, stained black with silver (arrow), is digested (see the lower half of **A**). **B**, Immunofluorescence showing aggregates of C3 in the tubular basement membrane (right) as well as within the glomerulus (left). Such tubular basement membrane aggregates are common in lupus nephritis, being found in 60% to 65% of biopsy specimens overall and with increasing frequency from class II (20%) to class IV (75%).

Figure 25.10 Vascular damage in lupus nephritis. Thrombus (arrow) occludes a glomerular capillary loop in this class IV biopsy specimen. Such a thrombus contains platelets and cross-linked fibrin as well as immunoglobulins and thus has some characteristics of true thrombus. Note also the subepithelial aggregates, spike formation, and double contouring of the capillary walls, all typical of class IV and active class III biopsy specimens. (Silver methenamine/hematoxylin.)

with severe proliferative nephritis, or a thrombotic microangiopathy. The last is most often found in patients who are APA positive with prior evidence of coagulation events and may occur in conjunction with a proliferative GN.¹¹⁻¹³

Transformation of Histologic Appearance and “Silent” Lupus Nephritis

Serial biopsy specimens often show transformation from one to another histologic glomerular class.⁴ Some patients with increased clinical activity will transform from a more benign or less proliferative class (ISN class II or class V) to a more active proliferative lesion (ISN class III or class IV). This is often heralded by increasing proteinuria and active urinary sediment. With successful treatment, other patients will transform from a proliferative class (ISN class III or class IV) to a more predominant membranous pattern (ISN class V).

Extremely uncommon are patients who have active proliferative LN on biopsy but no clinical or urinary sediment changes to indicate active disease and normal anti-dsDNA and serum complement levels, so-called silent LN or anephritic nephritis.² If the urine sediment is carefully checked, most patients with proliferative lesions will have microhematuria and often erythrocyte casts.

Clinical and Histopathologic Correlations and Other Correlates of Outcome

In general, the clinical correlates of the ISN and WHO classification systems are similar.^{3,4} Patients assigned to ISN class I usually have no evidence of clinical renal disease. Likewise, patients in ISN class II may have elevated anti-dsDNA or low complement levels, but in general, their urinary sediment is inactive, hypertension is infrequent, the GFR is preserved, and proteinuria is rarely above 1 g/24 h. Patients with class I and class II biopsy findings have an excellent renal prognosis unless they transform to another pattern. An exception to this presentation are lupus patients who present with minimal change nephrotic syndrome or lupus podocytopathy.²¹ They have the sudden onset of nephrotic syndrome with renal biopsy specimens showing no abnormalities on LM or class I or class II changes with extensive foot process effacement.

Patients with active ISN class III A or A/C often have microhematuria, hypertension, low complement levels, and proteinuria. From one quarter to one third of patients will have the nephrotic syndrome, and up to one in four will have an elevated serum creatinine concentration at renal biopsy. Patients with focal glomerular scarring (ISN class III C) usually have hypertension and reduced renal function but without active urinary sediment. Patients with mild proliferation in only a few glomeruli generally respond well to therapy, with less than 5% progressing to renal failure during 5 years of follow-up. Others with more glomerular involvement or with necrotizing features and crescent formation have a prognosis similar to that of class IV A patients. Whether patients with “severe” focal segmental proliferative class III have a worse prognosis than do those with diffuse proliferative class IV lesions is controversial.²²

Patients with ISN class IV A classically have high serologic activity (low serum complement and high anti-dsDNA binding activity) along with active urinary sediment, hypertension, heavy proteinuria, and reduced GFR. Class IV diffuse proliferative disease carries the worst renal prognosis in most series, although this is greatly influenced by prognostic features such as racial background, socioeconomic factors, and renal features at presentation. Patients with segmental diffuse proliferative class IV S may fare worse than those with diffuse global involvement class IV G, although this remains controversial.¹⁷

ISN class V patients typically present with proteinuria and features of the nephrotic syndrome. However, at biopsy, up to 40% will have subnephrotic proteinuria, and up to 20% will have less than 1 g/24 h of proteinuria. Patients with ISN class V typically have less clinical renal and serologic activity. Some develop what appears to be idiopathic nephrotic syndrome before developing other features of lupus. ISN class V patients are predisposed to thrombotic complications, such as renal vein thrombosis and pulmonary emboli.²⁰ Ten-year renal survival rates are 75% to 85%.

Advanced sclerotic LN, ISN class VI, is usually the result of “burnt-out” class III or class IV LN. Many patients will nevertheless have persistent microhematuria and some proteinuria along with hypertension and a decreased GFR.

Other Histologic Prognostic Factors

Features of reversible (active) or irreversible (chronic) damage on biopsy may be able to predict the course of LN patients. Some^{3,4} but not all²³ investigators have found that patients with a higher activity index or chronicity index* are more likely to progress to renal failure. Consistently, the renal prognosis is poor if biopsy specimens show extensive glomerulosclerosis or interstitial fibrosis.^{1,3,4,19,24} Whereas there is disagreement about the value of the individual activity index or chronicity index, patients with high degrees of both activity and chronicity on biopsy (activity index >7 plus chronicity index >3) fare poorly, as do those with the combination of cellular crescents and interstitial fibrosis on biopsy. Finally, certain features found on repeated renal biopsy at 6 months predict 5-year progression to renal failure, including ongoing inflammation with cellular crescents and macrophages in the tubular lumina, persistent immune

*Calculated by grading on each biopsy specimen the various histologic features of activity [indicated by glomerular cellular proliferation, leukocyte infiltration, fibrinoid necrosis or karyorrhexis, cellular crescents, hyaline thrombi or wire loops, and tubulointerstitial mononuclear cell infiltrates] or chronicity [indicated by glomerulosclerosis, fibrous crescents, interstitial fibrosis, and tubular atrophy] and summing the scores.

Survival in Lupus and Lupus Nephritis			
Period	5-Year Survival (percent)*		
	All Lupus	Lupus Nephritis	Class IV Nephritis
1953–1969	49	44	17
1970–1979	82	67	55
1980–1989	86	82	80
1990–1995	92	82	82
2000–2010	95–100	95–100	90–95

Figure 25.11 Survival in lupus and lupus nephritis. Five-year actuarial survival for lupus, lupus nephritis, and World Health Organization class IV nephritis during the periods shown. *Weighted mean of published series. (Modified from references 36,40,42).

deposits (especially C3), and persistent subendothelial and mesangial deposits.²⁵ The finding of both crescents and interstitial fibrosis persisting on the 6-month biopsy specimen led to a very poor renal outcome.

NATURAL HISTORY

The natural history of LN in the modern era is unknown because virtually all patients with severe renal involvement receive therapy directed at their renal lesions. Fifty years ago, few patients with severe LN survived more than a few years, and half of those with even less severe forms of LN died within 5 years. Most patients today have a gratifying response to early treatment, followed by relatively quiescent disease under continuing immunosuppression that can be tapered off eventually (Fig. 25.11). Some patients will continue to have no disease activity; others will relapse with time. The frequency of relapse depends not only on the underlying disease severity but also on the intensity and duration of continued immunosuppression.

End-stage renal disease (ESRD) now affects 8% to 15% of patients with LN. Rare patients with progressive LN leading to dialysis may regain enough renal function to terminate dialysis. A renal biopsy is often useful to determine whether the disease is still active and potentially treatable or all chronic and irreversibly scarred.

In patients with active LN, fatal infections often associated with persistent extrarenal disease activity are the most common cause of death. Studies confirm that almost half of all lupus deaths are the result of excess cardiovascular mortality, often later in the course of the disease and particularly from premature myocardial ischemia (see the section on **antiphospholipid antibodies and atherosclerotic and other complications**).

Multiple factors have been associated with outcomes in LN, but the interaction between these factors has not been clearly elucidated. Epidemiologic predictors include race, with African Americans and Hispanic Americans faring worse^{26–29}; those of Southeast Asian descent have more severe disease than other Asians or Caucasians do. Male gender, younger age (<24 years), and lower socioeconomic status, independent of race, are associated with a worse renal outcome.^{28,29} Laboratory outcome predictors include the histologic features discussed before, higher baseline serum creatinine concentration or greater baseline proteinuria, hypertension, severe anemia, thrombocytopenia, and hypocomplementemia with elevated anti-dsDNA levels. Clinical

management predictors include delay in the onset of therapy, degree of reduction of proteinuria with treatment, and nephritic relapse.

TREATMENT

It is useful to divide the treatment of patients with active proliferative LN into an induction phase and a maintenance phase. The induction phase deals with acute life- or organ-threatening disease, which often affects multiple organ systems. The maintenance phase focuses on the long-term management of chronic, more or less indolent disease and the management of nonhealing scars of disease and of increased cardiovascular and malignancy risk. Here, protection from the side effects of therapy and prevention of flares are more important.

Use of the ISN biopsy classification (see Fig. 25.3) can serve as a guide to initial therapy.^{1–4,30} In general, patients assigned to ISN class I and class II need no therapy directed at the kidney. The majority of patients will have a benign long-term outcome, and the potential toxicity of any immunosuppressive regimen will negatively alter the risk-benefit ratio of treatment. An exception is the group of lupus patients with minimal change syndrome or lupus podocytopathy (see earlier discussion). These patients respond to a short course of high-dose corticosteroids in a fashion similar to patients with minimal change disease (MCD).²¹ It is in patients with active focal proliferative LN (ISN class III A and III A/C), active diffuse proliferative LN (ISN class IV A and IV A/C), and membranous lupus (ISN class V) that combination corticosteroid and immunosuppressive therapy is most widely used.

The goal of induction therapy is to induce a renal remission. Studies have varied in their definition of remission, but this typically requires a reduction in proteinuria below 0.5 g/24 h or urine protein to creatinine ratio below 0.5 g/g, absence of glomerular hematuria or red cell casts, and normalization or at least stabilization of GFR. Subsequent flare is then defined by an isolated increase in proteinuria, typically at least doubling and above 1 g/24 h, as a proteinuric flare; or by the appearance of glomerular hematuria or red cell casts with proteinuria, with or without hypertension and a decline in GFR, as a nephritic flare.³¹

Evidence in support of different therapeutic agents and regimens has emerged from clinical trials conducted during the last 30 years. It is important to treat the conclusions of many of these trials with caution because many are of small size and have been uncontrolled or nonblinded, and LN is heterogeneous in its presentation and response to therapy. As toxicity of therapy is now a major factor in mortality and morbidity, claims of efficacy have to be carefully balanced against adverse events. Other factors, such as ethnicity, referral practice, center experience, and use of concomitant medications, vary between studies and over time, which reduces the generalizability of some study results. Consensus statements have addressed the methodology and terminology used in clinical studies of LN.³¹

The Treatment of Proliferative Lupus Nephritis: Induction Phase

Corticosteroids

Corticosteroids used in conjunction with other immunosuppressives are commenced at high dose: either prednisolone (1 mg/kg/day or 60 mg/day) or intravenous methylprednisolone infusions (0.5 to 1.0 g daily for 1 to 3 days), followed by oral prednisone (0.5 mg/kg/day). The oral dose is then reduced stepwise

to approximately 10 mg/day by 3-6 months. Cosmetic effects, risk of gastrointestinal ulceration, hypertension, psychoses, and enhanced risk of infectious complications have led to attempts to minimize prolonged courses of high-dose corticosteroid therapy in lupus patients. Some small uncontrolled trials suggested that intravenous pulse therapy is either more effective or less toxic than high-dose oral therapy.

Cytotoxic Agents

Cytotoxic agents in conjunction with corticosteroids play a major role in many induction regimens for LN.³²⁻³⁵ Cyclophosphamide is a powerful inhibitor of B cells as well as of other phases of the immune response. Both daily oral and intravenous pulses of cyclophosphamide have been effective in LN,³⁶ but intravenous therapy involves a lower cumulative exposure to cyclophosphamide and less frequent cytopenias, enables enhanced bladder protection, and avoids problems of nonadherence.

Studies of the U.S. National Institutes of Health initially established a role for every-third-month intravenous pulses of cyclophosphamide in preventing renal failure in patients with diffuse proliferative LN. Subsequent randomized, controlled trials in patients with severe proliferative LN³² established that six pulses of intravenous cyclophosphamide at monthly intervals (0.5 to 1 g/m²/hr) followed by pulses every 3 months along with low-dose corticosteroids were effective and prevented relapses better than a 6-month course alone did. A controlled trial established that pulse cyclophosphamide, when it is given with monthly pulses of methylprednisolone, led to better long-term GFR than did either regimen alone.³³ Follow-up of these patients showed that the regimen of intravenous pulse cyclophosphamide plus methylprednisolone had no more side effects than the regimen using pulses of cyclophosphamide alone. Nevertheless, side effects were significant (see later discussion) in both therapeutic arms of this study.³³ A study used intravenous cyclophosphamide to induce remissions in 59 patients with severe LN, almost half African American, with a mean serum creatinine concentration of 1.6 mg/dl and average urinary protein to creatinine ratio (g/g) of more than 5.³⁴ With six to eight monthly intravenous doses, 83% had a remission, with mean creatinine reduction from 1.59 to 0.97 mg/dl, mean urinary protein to creatinine ratio declining from 5.1 to 1.7, and correction of hypertension and serologic abnormalities. It is clear that this regimen of intravenous cyclophosphamide is effective in induction therapy, and most studies using newer regimens have focused on achieving this high induction response rate with fewer side effects.

A trial by the Euro-Lupus Group tried to decrease the risk of side effects from cyclophosphamide therapy without sacrificing efficacy.³⁵ This study randomized 90 predominantly Caucasian patients with diffuse or focal proliferative LN or membranous plus proliferative disease to receive either standard six monthly pulses of cyclophosphamide (0.5 to 1 g/m²/month) followed by every-third-month infusions or a shorter treatment course consisting of 500 mg of intravenous cyclophosphamide every 2 weeks for six doses (total dose, 3 g), then switching to azathioprine maintenance therapy (2 mg/kg/day). Both regimens were equally effective in renal and extrarenal outcomes. The shorter regimen had less toxicity with significantly less severe and total infections as a complication of treatment. Subsequent reports after 5 and 10 years continued to find no differences in outcome between treatment groups.³⁶ Although this regimen has not yet been tested in significant populations of African Americans or Hispanics, it is being widely adopted in clinical practice as a method to avoid major cyclophosphamide side effects.

Mycophenolate Mofetil

Several recent controlled trials and subsequent meta-analyses have examined the role of mycophenolate mofetil (MMF) in the induction of remission of severe LN.³⁷⁻⁴² One evaluated 42 Chinese patients randomized to receive either 12 months of MMF or 6 months of oral cyclophosphamide followed by azathioprine for 6 months.³⁸ Both groups received concomitant tapering doses of corticosteroids. At 12 months, the number of complete or partial remissions and relapses was not different between the regimens. Infections were less in the MMF arm, and mortality was all in the cyclophosphamide group (0% versus 10%). Longer follow-up confirmed the benefits of the MMF group.⁴¹ A second trial also in a Chinese population evaluated 46 patients treated with either pulse intravenous cyclophosphamide or MMF for 6 months.³⁹ Patients treated with MMF had greater reductions in proteinuria and greater improvement on renal biopsy.

Another trial examined 140 patients (>50% African Americans) with proliferative LN.⁴⁰ One half was randomized to intravenous cyclophosphamide monthly pulses and one half to MMF, each in conjunction with a fixed tapering dose of corticosteroids as induction therapy during 6 months. Complete and partial remissions at 6 months were significantly more common in the MMF arm. Side effect profile was better in the MMF group. At 3 years, rates of renal failure, ESRD, and mortality were similar.

A 370-patient international trial of induction therapy with either MMF or monthly intravenous cyclophosphamide yielded comparable rates of complete and partial remission as well as equivalent resolution or stability of all renal and extrarenal parameters after 6 months,⁴² even in the subgroup presenting with a GFR below 30 ml/min.⁴³ Mortality was similar in both groups.

Given these recent induction trials, MMF is one of the recommended first-choice regimens for inducing a remission in severe active proliferative LN (Fig. 25.12).

Other Immunosuppressive Strategies

Azathioprine and cyclosporine have been used in combination with corticosteroids for the induction of remission in LN. A recent randomized trial comparing azathioprine with cyclophosphamide found no difference in eventual outcome but more relapses and more patients doubling their serum creatinine concentration in the azathioprine group.⁴⁴ One innovative approach is to use multitargeted therapy with three immunosuppressive agents, each with different toxicities. In a recent trial, the use of MMF along with tacrolimus and corticosteroids proved superior to intravenous cyclophosphamide plus corticosteroids in inducing remissions at both 6 months and longer in a group of patients with proliferative lesions superimposed on membranous LN.⁴⁵

Plasma exchange has been added to other induction therapies (e.g., cyclophosphamide) in several controlled randomized trials. Although no trial demonstrated significant benefit in terms of renal or patient survival or in reduction of proteinuria or improvement of GFR, suggesting that the routine use of plasma exchange was not justified in LN, this procedure continues to be used for those with refractory or rapidly progressive renal disease in some centers. Intravenous gamma globulin has given encouraging results as adjunct therapy for patients with severe lupus and nephritis in preliminary studies. A major problem is that there is no standard accepted preparation of intravenous IgG, and a fall in GFR may be seen during administration that is not always reversible.

For patients with life-threatening resistant disease, small pilot studies have used total lymphoid irradiation and immunoablation

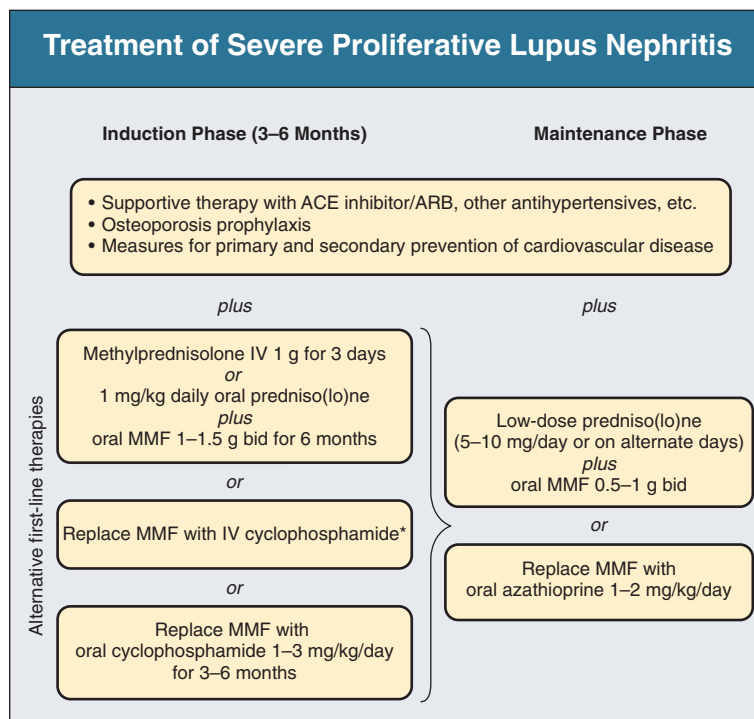

Figure 25.12 Treatment of severe proliferative lupus nephritis (ISN class III A or III A/C or ISN class IV A or IV A/C). ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; MMF, mycophenolate mofetil. *Use either 0.5–1 g/m² monthly for 6 months or follow the Euro-Lupus group protocol (see text).

by high-dose cyclophosphamide and antithymocyte globulin, with or without reconstitution with autologous stem cells. These approaches have led to sustained treatment-free remissions but are toxic and have a treatment-related mortality.^{46,47} Their role in SLE therapy remains to be determined.

Biologic Agents

With respect to targeted biologic agents, early studies of monoclonal antibodies directed against B- and T-cell costimulation (anti-CD40 ligand) have proved unsuccessful, in part due to lack of efficacy and in part due to thrombotic complications. New trials using CTLA4Ig (abatacept) to block T- and B-cell costimulation are under way. In small pilot trials, rituximab, an anti-CD20 monoclonal antibody that depletes B cells, induced remissions in some patients with severe LN, including some who have failed cyclophosphamide or MMF therapy.⁴⁸ More recently, 140 patients with severe LN were randomized to rituximab versus placebo added to MMF and tapering dose of corticosteroids.⁴⁹ Both in this trial and in a trial in SLE patients without renal disease,⁵⁰ rituximab failed to add a major benefit in therapy. Whereas these results do not support the routine use of rituximab, the nature of the trial designs using rituximab in addition to conventional therapy and relatively short follow-up may have contributed to the negative results. Thus, the role of rituximab in the treatment of LN currently remains unclear. Inhibition of the B cell–stimulating cytokine (BlyS) by a monoclonal antibody, belimumab, has proved superior to placebo in extrarenal SLE. Other B-cell targeted therapies under investigation include a monoclonal antibody to CD22 (epratuzumab), a fully humanized anti-CD20 (ocrelizumab), and a soluble TACI (transmembrane activator and calcium-modulator and cyclophilin ligand interactor) receptor that inhibits B cell–stimulating cytokines (atacept).⁵¹

Summary of Evidence of Induction Agents

Although corticosteroids are routinely recommended for LN induction therapy, their combination with MMF is emerging

as the most attractive initial strategy because of the recent evidence supporting MMF and the desire to avoid toxicities associated with cyclophosphamide. However, approximately one third will not remit with MMF and corticosteroids, and a cascade of second- and third-line options needs to be considered when treatment is planned. Cyclophosphamide, azathioprine, cyclosporine, tacrolimus, and rituximab are alternatives in this setting. For the minority with progressive disease, the addition of intravenous corticosteroids, plasma exchange, and immunoglobulins is an option to be considered.

The Treatment of Proliferative Lupus Nephritis: Maintenance Therapy

In most patients, the acute renal disease will come under control by 3 months of therapy. By 6 months, almost all responders will have improving serologic markers (anti-DNA antibody levels, serum complement), improvement of GFR, and decline in proteinuria. Persistent but declining levels of proteinuria and some urinary sediment abnormalities at 6 months are not rare and do not indicate disease activity. The challenges once remission has been induced are to avoid flares of disease activity, to avoid smoldering activity leading to chronic irreversible renal scarring, and to prevent long-term side effects of therapy. A number of agents have been studied in maintenance regimens for LN patients once induction therapy has been completed.

Corticosteroids are a major component of treatment in the maintenance therapy for LN. To minimize the side effects of long-term corticosteroids, the dosage should be limited (e.g., predniso(lo)ne 5 to 15 mg/day), and osteoporosis prophylaxis should be given concomitantly (see Fig. 25.12). Both daily and alternate-day regimens have been used.

Meta-analyses unequivocally favor the additional benefit of using an immune suppressive agent during the maintenance therapy. During 10 to 15 years of follow-up, regimens of intravenous cyclophosphamide, oral cyclophosphamide, or oral

cyclophosphamide plus oral azathioprine showed less progression of renal scarring than with either prednisone- or azathioprine-alone regimens.

Whereas oral cyclophosphamide has been used for induction therapy in a number of trials, its use for longer than 3 to 6 months should be avoided because of toxicities of alopecia, cystitis and bladder cancer, and gonadal damage with early menopause. Timing of the intravenous cyclophosphamide pulse in coordination with the menstrual cycle and the use of leuprolide acetate have been attempted, but infertility remains a major complication of all women older than 30 years and especially those receiving longer than a 6-month induction course.

Azathioprine in doses of 1 to 2.5 mg/kg/24 h has proved remarkably safe in the very long term. Macrocytosis, leukopenia, and interaction with allopurinol are all potential side effects along with the ever-present risk of infection from immunosuppression. Pancreatitis and hepatotoxicity are rare side effects. Azathioprine has a much lower oncogenic potential than cyclophosphamide, and pregnancy during maintenance azathioprine therapy may be relatively safer compared with other immunosuppressive agents (see later discussion). Two studies used azathioprine successfully as maintenance therapy after induction with a short or long course of cyclophosphamide or MMF.^{34,35}

MMF has been used to maintain remission after MMF induction.^{34,36} Both azathioprine and MMF have proved superior to continued every-third-month intravenous cyclophosphamide at maintaining remissions and preventing mortality or ESRD.³⁴ Major side effects were all significantly lower in the group receiving the oral agents. The teratogenicity of MMF complicates its long-term use in women whose lupus is in remission. A recent study of 227 patients who achieved remission of lupus nephritis after either IV cyclophosphamide or MMF induction therapy and were rerandomized to three years maintenance with either MMF or azathioprine showed clear superiority of the MMF at maintaining renal function, remissions, and preventing ESRD.^{51a}

Cyclosporine has been used with limited success as monotherapy for maintenance of remissions in patients with proliferative LN, with efficacy similar to that of azathioprine.⁵² It has a greater role in the treatment of membranous lupus to reduce proteinuria and in combination with other medications to maintain remission of proliferative LN. Toxicity is discussed in Chapter 97. Tacrolimus has similar toxicities and is being used as an alternative to cyclosporine in recent trials in glomerular diseases.⁴⁵

A summary of disease-specific treatment is given in Figure 25.12 for both induction and maintenance phases of treatment of severe proliferative LN. General renoprotective measures should follow the recommendations outlined in Chapter 76. Other agents used to treat extrarenal findings in lupus patients, including NSAIDs, antimalarials, androgens, and fish oil, have not shown benefit in terms of renal disease in SLE patients with the exception of a study with antimalarials.

The majority of patients will be maintained in remission by this treatment; but in a few cases, the initial disease is so severe that it does not come under control, or frequent early relapses are seen. An approach to the management of such patients is summarized in Figure 25.13.

Membranous Lupus Nephropathy

In the past, investigators reported different renal survival rates for different populations with membranous lupus nephropathy. In part, this was due to problems with the WHO classification,

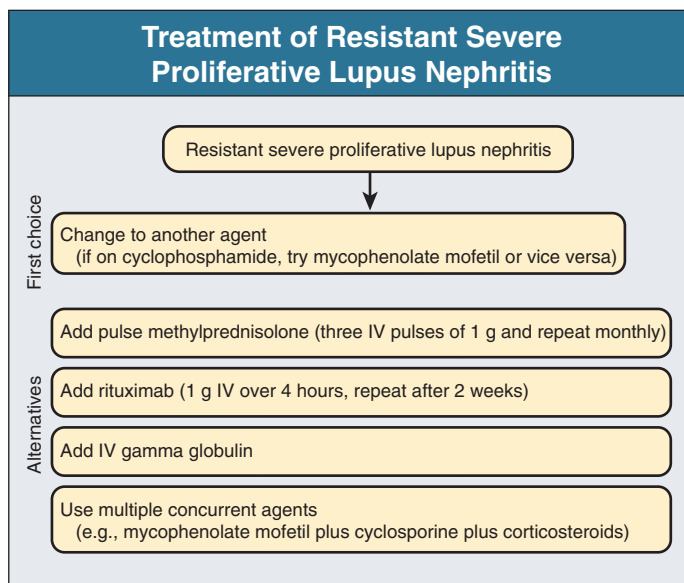

Figure 25.13 Treatment of resistant severe proliferative lupus nephritis.

which included proliferative lesions superimposed on pure lupus membranous nephropathy (WHO class Vc and Vd) along with those with only predominantly membranous features (Va and Vb) (see Fig. 25.3).¹⁷ Moreover, patients with subnephrotic proteinuria and pure membranous lupus nephropathy do extremely well regardless of treatment options, and no consensus of management has emerged yet for this group of patients.

In a controlled trial, 42 patients with lupus WHO class Va and Vb were randomized to receive monthly pulses of intravenous cyclophosphamide, oral cyclosporine, or oral prednisone for a year.⁵³ The patients had preserved GFR but a mean proteinuria of almost 6 g daily. At last follow-up, there were more complete and partial remissions in the cyclophosphamide and cyclosporine groups than in the prednisone group. Remissions occurred more quickly in the cyclosporine group, but there were fewer relapses in the cyclophosphamide group. Patients who relapsed or failed to respond to cyclosporine could subsequently be brought into remission with intravenous cyclophosphamide. Two recent trials of MMF versus intravenous cyclophosphamide induction in LN included 84 patients with pure membranous nephropathy among the 510 patients enrolled.⁵⁴ Remissions, relapses, and courses were similar in the patients treated with oral MMF and intravenous cyclophosphamide induction therapy. Azathioprine along with corticosteroids has also been successful in some populations of membranous LN.

Thus, for patients with membranous nephropathy who have subnephrotic levels of proteinuria and a preserved GFR, we recommend (Fig. 25.14) either conservative therapy with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers and statins or a short course of corticosteroids or cyclosporine. For fully nephrotic patients and those at higher risk for progressive disease, there are multiple treatment options including a course of oral cyclosporine or tacrolimus, monthly intravenous pulses of cyclophosphamide, and MMF or azathioprine plus corticosteroids.⁵⁵ In all, the treatment regimen will have to be at least 6 months, and avoidance of side effects is paramount.

Remissions and Relapses and Stopping Therapy

Achieving a remission of LN predicts an improved long-term outcome. In one study, the 5-year patient and renal survival was 95% and 94%, respectively, for the group achieving remission and only 69% and 45%, respectively, for the group not achieving a remission.⁵⁶ Partial remission was also associated with improved outcomes compared with no remission. Predictors of remission included lower baseline serum creatinine concentration, lower baseline urinary protein excretion, better renal histologic class by the WHO or ISN system, lower chronicity index, stable GFR after 4 weeks of therapy, and Caucasian race.

The relapse rate for LN has ranged from 35% to almost 60%, depending on which population is studied, what criteria for relapse are used, and what maintenance therapy is used.^{57–59} Elevation of anti-dsDNA and decline in serum complement levels may presage relapse. However, a number of patients maintain elevated anti-dsDNA levels for years without relapse, and most clinicians prefer not to treat “serologic” activity alone in the absence of clinical disease activity. A major value of a normal anti-dsDNA level is to indicate a lower risk of relapse after treatment reduction or withdrawal in the chronic phase of maintenance therapy.⁶⁰

Monitoring of nephritis should include regular estimates of blood pressure, GFR, proteinuria, and urinary sediment. The role of repeated renal biopsy is controversial; routine follow-up biopsies have prognostic value and permit assessment of activity and progression of chronicity. Repeated biopsy at the time of flare will confirm the diagnosis of increased activity and will identify changes in histologic class, and repeated biopsy for a declining GFR will identify whether there are active lesions potentially modifiable by an increase in therapy. Although some

patients will relapse many years after remission and disease quiescence, it is often possible to stop treatment entirely in many patients after 5 years or more, when the disease process has apparently “burned out.” Stable GFR, lack of proteinuria, and normal immunologic test results predict successful discontinuation of immune suppressives. However, the longer corticosteroids and immunosuppressive drugs are continued, the lower the relapse rate, and it was notable in the 10-year follow-up of the Euro-Lupus study that 75% of patients were still receiving one of these interventions.³⁶

Antiphospholipid Antibodies and Atherosclerotic and Other Complications

A significant percentage of lupus patients will have some form of APA detectable.^{11–13} The risk of thrombotic episodes is highest with lupus anticoagulant and somewhat lower with anti- β_2 -glycoprotein 1 and anticardiolipin antibodies. Disappearance of APA is unusual despite complete clinical remissions with immune suppressives and normalization of anti-dsDNA levels and other immunologic markers. There is an increased risk of hemorrhage after renal biopsy in the presence of the antiphospholipid syndrome, most likely caused by vascular damage to renal arteries that impedes hemostasis. Clinical manifestations and treatment of patients with APA are discussed further in Chapter 27.

Active organ involvement by lupus itself and infectious complications of treatment are being replaced by atherosclerotic complications as leading causes of morbidity and mortality.^{61,62} Patients with lupus have increased risk of atherosclerotic complications compared with age-matched controls and greater atherosclerotic plaque burden. Young women with SLE have a

risk of heart attack that is 50 times greater than that of healthy women, and even older women with SLE have 2.5 to 4 times the risk of myocardial infarction.¹⁴ Many patients with active lupus have abnormalities of numerous cardiovascular risk factors, including hyperlipidemia, metabolic syndrome, hypertension, and systemic inflammation. Even after adjustment for all routine risk factors, SLE patients have a 7 to 10 times higher risk of nonfatal myocardial infarction and a 17 times higher risk of fatal myocardial infarction.¹¹ Reduction of atherosclerotic risk should be focused on tight control of blood pressure (to 130/80 mm Hg or lower), use of statins to correct lipid abnormalities, and suppression of active inflammatory disease activity.

Pregnancy in some lupus patients has been associated with flares of lupus activity either in the third trimester or shortly after delivery (see Chapter 43). It is important that therapy not be reduced in patients planning a pregnancy as treatment reduction increases the relapse risk. MMF and cyclophosphamide are teratogenic and should be withdrawn before conception. Azathioprine, cyclosporine, and corticosteroids have been used during pregnancy, although they are not without the potential for side effects. A short course of high-dose corticosteroids in the immediate postpartum period has been advocated to reduce the risk of flare at that time. The presence of immune suppressive and other drugs in breast milk needs to be considered in mothers planning to breast-feed. Compared to women with out lupus, SLE patients more commonly miscarry and deliver low-birth-weight babies. Studies suggest that oral contraceptive use is not associated with increased severe or mild to moderate flares of disease activity.⁶³ The use of hormone replacement therapy has been associated with only a small increase in the incidence of mild to moderate flares of disease in a study of more than 350 menopausal SLE patients.⁶⁴

Osteoporosis and avascular necrosis of bone have become important long-term health issues for many lupus patients.¹¹ Women with SLE have five times higher fracture rates than normal women do. Minimizing the use of corticosteroids, especially the maintenance dose, and use of vitamin D and calcium supplements along with other agents to reduce bone loss are important.

End-Stage Renal Disease and Renal Transplantation

No more than 10% to 15% of lupus patients develop ESRD, and lupus represents only 1% to 2% of all patients with ESRD.⁶⁵ Many patients will have inactive burnt-out disease by the time they reach ESRD. Some who develop irreversible renal failure rapidly may still have active disease and require vigorous treatment while receiving renal replacement therapy. Survival of lupus patients on dialysis is comparable to that of other primary renal diseases.⁶⁵ Some patients with antiphospholipid syndrome require anticoagulation to prevent arteriovenous fistula or graft clotting.

Transplantation in lupus patients, whether from cadaveric or living donors, can be performed with only a few extra precautions. Outcomes in SLE patients undergoing transplantation are similar to those of patients with other diseases.^{66,67} Crossmatching of donors with lupus patients may be difficult because the sera may contain antilymphocyte autoantibodies, rendering a false-positive "crossmatch." These can usually be "absorbed out" in testing and, in general, do not influence the course of the allograft. Immunosuppression, rejection episodes or graft loss, and infectious complications are similar to those of non-lupus

patients.⁶⁷ Many clinicians prefer to wait until a patient has been maintained on 6 to 12 months of dialysis to be certain the lupus is not active at the time of transplantation. For those patients who are clinically inactive but retain serologic activity with elevated anti-DNA antibody levels, starting of transplant immunosuppressives in a prophylactic fashion several weeks to a month before transplantation with use of a live donor may suppress the serologic activity.

Thrombosis may be a problem after transplantation, especially in patients with APA.^{11-13,20,68} Renal transplant arterial and venous as well as intraglomerular thromboses have been reported. Anticoagulation shortly after transplantation should be reserved for those APA-positive patients with a prior thrombotic event but in such cases may yield good results.

Recurrent disease in the allograft in patients with LN is discussed in Chapter 104.

Renal Amyloidosis and Glomerular Diseases with Monoclonal Immunoglobulin Deposition

Pierre M. Ronco, Pierre Aucouturier, Bruno Moulin

The glomerular capillaries are a favorite site for the deposition of abnormal proteins. In most cases, the resulting diseases are caused by a monoclonal immunoglobulin subunit, and those can be classified into two categories by electron microscopy (Fig. 26.1). The first category includes diseases with fibril formation, mainly amyloidosis, and diseases with microtubule formation, including cryoglobulinemic (see Chapter 21) and immunotactoid glomerulonephritis (GN). The second category is characterized by nonorganized electron-dense granular deposits. They are localized along basement membranes in most tissues, especially in the kidney, and define a disease now termed monoclonal immunoglobulin deposition disease (MIDD). In some cases, monotypic immune complex-like deposits are observed in the setting of proliferative GN.

RENAL AMYLOIDOSIS

General Characteristics of Amyloidosis

Definition

Amyloidosis is a generic term for a family of diseases defined by morphologic criteria. The diseases are characterized by the deposition in extracellular spaces of a proteinaceous material. Amyloid deposits are composed of a felt-like array of 7.5- to 10-nm-wide rigid, linear, nonbranching, aggregated fibrils of indefinite length.¹ One amyloid fibril is made of two twisted 3-nm-wide filaments, each displaying the typical “cross- β ” structure,¹ where antiparallel β -sheets are perpendicular to the filament axis.

Amyloid Precursor–Based Classification

Amyloidoses are classified by the type of precursor protein that composes the main component of fibrils (Fig. 26.2).² The amyloidogenic propensity is related to the ability of this precursor to form intermolecular β -sheets. Besides these structural properties, which may relate to genetically transmitted mutations, the amyloidogenic potential is enhanced by overproduction or impaired clearance of the precursor.

Renal amyloidoses mostly include immunoglobulin light chain (AL) and systemic secondary (AA) amyloidoses. Other precursors, such as transthyretin, fibrinogen, apolipoprotein A-I, and lysozyme, are responsible for rare familial cases.

Other Components of All Amyloid Fibrils

Glycosaminoglycans (GAGs) are tightly associated with amyloid fibrils. GAGs are polysaccharide chains made of repeating hyaluronic acid–hexosamine units normally linked to a protein

core, thus forming proteoglycans. Proteoglycans, mostly of the heparan sulfate type, appear to induce and to stabilize the β -pleated amyloid structure.

Another constituent of all amyloid deposits is serum amyloid P component (SAP). SAP is resistant to proteolytic digestion, and coating of amyloid fibrils with SAP could result in their protection from catabolism. The high affinity of SAP toward amyloid was exploited for diagnosis, location, and monitoring of the extent of systemic amyloidosis by scintigraphy with [¹²⁵I]-SAP.

General Mechanisms of Fibrillogenesis

Amyloidogenesis involves a nucleation-dependent polymerization process. Formation of an ordered nucleus is the initial and thermodynamically limiting step, followed by addition of monomers and elongation of the fibrils.³ Fibrillogenesis may involve several mechanisms of processing of the amyloid precursor, including partial proteolysis and conformational modifications. Conformational changes lead to a soluble, partially folded intermediate, whose subsequent ordered self-assembly results in fibril formation. Macrophages have a central role in AA amyloidosis by providing the intralysosomal processing of the precursor. In AL amyloidosis, the variable domain of the light chain V_L is the main component, which suggests a role of partial proteolysis of the light-chain precursor.

Pathology

On light microscopy, the deposits are extracellular, eosinophilic, and metachromatic. After Congo red staining, they appear faintly red (Fig. 26.3A) and show characteristic apple-green birefringence under polarized light (Fig. 26.3B). Metachromasia is also observed with crystal violet, which stains the deposits red.

The earliest lesions are located in the mesangium (see Fig. 26.3A), along the glomerular basement membrane (GBM), and in the blood vessels. Mesangial deposits are primarily in the mesangial matrix and spread from lobule to lobule until eventually the whole mesangial area is replaced. Amyloid deposits may also infiltrate the GBM or be localized on both sides of it. When subepithelial deposits predominate, spikes similar to those seen in membranous nephropathy (MN) may be observed. Advanced amyloid typically produces a nonproliferative, noninflammatory glomerulopathy and marked enlargement of the kidney. The amyloid deposits replace the normal glomerular architecture, with a consequent loss of cellularity. When glomeruli become massively sclerotic, the deposits may be difficult to demonstrate by Congo red staining. Electron microscopy may be helpful then and also in the very early stages, which may not be detected by

Glomerular Diseases with Tissue Deposition or Precipitation of Monoclonal Immunoglobulin Components

Figure 26.1 Glomerular diseases with tissue deposition or precipitation of monoclonal immunoglobulin components.

light microscopy examination in patients presenting with the nephrotic syndrome. Amyloid deposits are characterized by randomly oriented, nonbranching fibrils with an 8- to 15-nm diameter (Fig. 26.4).

Except for fibrinogen amyloidosis, which characteristically does not affect renal vessels, the media of the blood vessels is prominently involved at early stages. Vascular involvement may predominate and occasionally occurs alone, particularly in AL amyloidosis. Deposits may also affect the tubules and the interstitium, leading to atrophy and disappearance of the tubular structures and to interstitial fibrosis.

Given the heterogeneity of amyloidoses, immunohistology should be routinely performed (Fig. 26.3C). Immunohistochemical classification of amyloid type is possible in most cases. Immunohistology with antibodies specific for immunoglobulin chains may be more difficult to interpret than that with anti-AA antiserum, perhaps because of the absence or inaccessibility of light-chain epitopes. A genetic cause should be sought in all patients with amyloidosis in whom confirmation of the amyloid precursor cannot be obtained by immunohistochemistry.⁴

Classification of Amyloidoses				
Amyloid Protein	Precursor	Distribution	Type	Syndrome or Involved Tissues
AA	Serum amyloid A	Systemic	Acquired	Secondary amyloidosis, reactive to chronic infection or inflammation including hereditary periodic fever (FMF, TRAPS, HIDS, FCU, and MWS)
AApoAI	Apolipoprotein A-I	Systemic	Hereditary	Liver, kidney, heart
AApoAII	Apolipoprotein A-II	Systemic	Hereditary	Kidney, heart
Aβ	A β protein precursor	Localized	Acquired	Sporadic Alzheimer's disease, aging
		Localized	Hereditary	Prototypical hereditary cerebral amyloid angiopathy, Dutch type
Aβ2M	β_2 -Microglobulin	Systemic	Acquired	Chronic hemodialysis
ABri	Abri protein precursor	Localized or systemic?	Hereditary	British familial dementia
ACys	Cystatin C	Systemic	Hereditary	Icelandic hereditary cerebral amyloid angiopathy
AFib	Fibrinogen A α chain	Systemic	Hereditary	Kidney
AGel	Gelsolin	Systemic	Hereditary	Finnish hereditary amyloidosis
AH	Immunoglobulin heavy chain	Systemic or localized	Acquired	Primary amyloidosis, myeloma associated
AL	Immunoglobulin light chain	Systemic or localized	Acquired	Primary amyloidosis, myeloma associated
ALect2	Leukocyte chemotactic factor 2	Localized	Acquired ?	Kidney
ALys	Lysozyme	Systemic	Hereditary	Kidney, liver, spleen
APrP	Prion protein	Localized	Acquired	Sporadic (iatrogenic CJD, new variant CJD)
		Localized	Hereditary	Familial CJD, GSSD, FFI
ATTR	Transthyretin	Systemic	Hereditary	Prototypical FAP
			Acquired	Senile heart, vessels

Figure 26.2 Classification of amyloidoses. Entries in bold type indicate amyloid types with kidney involvement. The following proteins may also cause amyloidosis: calcitonin, islet-amyloid polypeptides, atrial natriuretic factor, prolactin, insulin, lactadherin, keratoepithelin, and Danish amyloid protein (which comes from the same gene as ABri and has an identical N-terminal sequence). CJD, Creutzfeldt-Jakob disease; FAP, familial amyloidotic polyneuropathy; FCU, familial cold urticaria; FFI, fatal familial insomnia; FMF, familial Mediterranean fever; GSSD, Gerstmann-Sträussler-Scheinker disease; HIDS, hyper-IgD syndrome; MWS, Muckle-Wells syndrome; TRAPS, tumor necrosis factor receptor–associated periodic syndrome. (Modified from references 5, 6.)

Immunoglobulin-Associated Amyloidosis (AL and AA)

Free immunoglobulin subunits, mostly light chains, secreted by a single clone of B cells, are the cause of the most frequent and severe amyloidosis affecting the kidney. Studies on the mechanisms of AL amyloidogenesis are made particularly difficult by the unique structural heterogeneity of the precursor: each monoclonal light chain is different from all others, so each patient is unique. The involvement of an immunoglobulin heavy chain in amyloidosis remains exceptional.⁷

Pathogenesis

Determinant factors are borne by the precursor light chain. In AL amyloidosis, there is a striking overrepresentation of the λ isotype, which is twofold to fourfold more frequent than the κ isotype. A rarely expressed homology family of light-chain variable regions, the $V_{\lambda 1}$ variability subgroup, is found only in amyloid-associated monoclonal immunoglobulins.

Amyloidogenicity is associated with physicochemical features including low-molecular-mass light-chain fragments in the urine, abnormal disulfide bonding of light chains, and low isoelectric point (pI). An analysis of nearly 200 light-chain sequences identified 12 positions in κ chains and 12 in λ chains where certain residues were associated with amyloidosis. Four

structural risk factors were shown to define most fibril-forming κ light chains.⁸ Because of their high dimerization constants, light chains from patients with AL amyloidosis may behave like antibodies with affinity for extracellular structures.

The tropism of organ involvement may be influenced both by the germline gene used for the light-chain variable region (V_L) and by somatic mutations occurring in the secreting clone.⁹ Patients expressing a monoclonal light chain of the $V_{\lambda 1}$ subgroup are more likely to present with dominant renal involvement and less frequent cardiac and multisystem disease.¹⁰ Patients with κ light chains are more likely to have dominant hepatic involvement. In addition, organ-specific environmental factors are also involved. For example, high intrarenal concentrations of urea enhance fibril formation by reducing the nucleation lag time.

Amyloid light chains may contribute directly to the pathogenesis, independent of extracellular fibril deposition. In the heart and the kidney at least, the infiltration alone does not correlate well with clinical manifestations. Light chains from amyloid patients incubated with mesangial cells induce a macrophage-like phenotype, whereas those from light-chain deposition disease patients induce a myofibroblast-like phenotype.¹¹

Epidemiology

The incidence of AL amyloidosis is nine per million per year. Fewer than one of four patients with AL amyloidosis is considered to have an overt immunoproliferative disease, which usually is multiple myeloma, although other forms are seen, such as Waldenström's macroglobulinemia. Amyloid deposits are found in approximately 10% of all patients with myeloma and in 20% of those with pure light-chain myeloma. The apparent prevalence of myeloma depends on the diagnostic criteria used. Epidemiologic characteristics of primary amyloidosis, that is, amyloidosis without overt immunoproliferative disease, and myeloma are not significantly different. The median age at diagnosis is 64 years in patients with primary amyloidosis, with a slight predominance of male patients.¹²

Clinical Manifestations

The main clinical symptoms at presentation are weakness and weight loss (Fig. 26.5). Except for bone pain, the initial symptoms in patients with and without myeloma are similar. However, nephrotic syndrome, orthostatic hypotension, and peripheral neuropathy are more frequent in patients with AL amyloidosis without myeloma.¹³ Amyloidosis is also different from many types of kidney disease in that the kidney is often enlarged and

Clinical and Laboratory Features at Presentation in 474 Patients with Proven AL-Amyloidosis

Features	Percentage
Initial symptoms	
Fatigue	62

hypertension is absent even when renal function is impaired. Proteinuria, mainly albuminuria, occurs in the absence of microscopic hematuria. Indeed, the presence of hematuria should prompt examination for a bleeding lesion in the urinary tract. Renal manifestations may also include renal tubular acidosis (mostly as a part of Fanconi syndrome; see Chapter 48) and polyuria-polydipsia (resulting from urinary concentration defect), when amyloid deposits occur around proximal tubules and Henle's loops (or collecting ducts), respectively.

AL amyloidosis may infiltrate almost any organ other than the brain and therefore can be responsible for a wide variety of clinical manifestations. Restrictive cardiomyopathy is found at presentation in up to one third of patients and causes death in about one half. Infiltration of the ventricular walls and the septum may be recognized by echocardiography. Amyloid may also induce arrhythmias and the sick sinus syndrome. Amyloid deposits in the coronary arteries may result in angina and myocardial infarction. Cardiac troponins and N-terminal pro-brain natriuretic peptide are sensitive markers of myocardial dysfunction and powerful predictors of overall survival in patients with AL amyloidosis.

Involvement of the gastrointestinal tract is common and can cause motility disturbances, malabsorption, hemorrhage, or obstruction. Macroglossia (Fig. 26.6) may interfere with eating and obstruct airways. Abnormalities of hepatic function are usually mild. Hyposplenism diagnosed by abnormal peripheral smear and liver spleen scan, commonly associated with splenomegaly, predisposes to fatal bacterial infections. Peripheral nerve involvement may result in a painful sensory polyneuropathy followed later by motor deficits. Autonomic neuropathy causing orthostatic hypotension, lack of sweating, gastrointestinal disturbances, bladder dysfunction, and impotence may occur alone or

Figure 26.6 Macroglossia in a patient with AL amyloidosis. (Courtesy Dr. S. Aractinji, Paris, France.)

Figure 26.7 Skin involvement in AL amyloidosis. Noninfiltrated purpuric macule of the superior eyebrow, very typical of AL amyloidosis. (Courtesy Dr. S. Aractinji, Paris, France.)

together with peripheral neuropathy. Orthostatic hypotension is one of the major hampering complications of AL amyloidosis, with some patients being bedridden. Skin involvement may take the form of purpura, characteristically around the eyes (Fig. 26.7), and ecchymoses, papules, nodules, and plaques, occurring usually on the face and upper trunk. AL amyloidosis may also infiltrate articular structures and mimic rheumatoid or an asymmetric seronegative synovitis. Infiltration of the shoulders may produce severe pain and swelling (shoulder pad sign).

A rare but potentially serious manifestation of AL amyloidosis is an acquired bleeding diathesis that may be associated with deficiency of factor X or factor IX or with increased fibrinolysis. It should be systematically sought before any biopsy of a deep organ. Widespread vascular deposits may also be responsible for bleeding. Prothrombin time and activated partial thromboplastin time measurements as well as determination of bleeding times are required to assess bleeding diathesis.

Monoclonal light chains can be detected by immunoelectrophoresis in 73% of the urine samples of patients with AL amyloidosis. The λ isotype is twice as frequent as the κ , contrasting with the 1:2 ratio of λ to κ observed in myeloma alone. With the use of more sensitive immunochemical techniques, a monoclonal immunoglobulin is found in the serum or the urine in nearly 90% of patients. The combination of immunochemical techniques and serum-free light-chain assay detects an abnormal result in 99% of patients.¹⁴

AL amyloidosis associated with IgM paraproteinemia characterizes a distinctive subset of patients who have a wider variety of underlying, often lymphoid clonal disorders (including 75% Waldenström's macroglobulinemia), usually low-level free light chains with a predominance of κ isotype, and higher prevalence of lymph node (31% versus 3%) and lung (17% versus 2%) involvement compared with patients with non-IgM monoclonal component.^{15,16}

Diagnosis

AL amyloidosis should be considered in any patient who presents with nephrotic-range proteinuria with or without renal impairment, nondilated cardiomyopathy, peripheral neuropathy, hepatomegaly, or autonomic neuropathy, whether or not a paraprotein can be detected in the serum or urine (Fig. 26.8). Particular vigilance should be maintained in patients with multiple myeloma or monoclonal gammopathy of undetermined significance (MGUS), especially of the λ isotype. Initial investigation should confirm the diagnosis of amyloidosis on tissue biopsy, and this should be followed by investigations to establish the type of amyloid present and the extent of organ involvement.

All patients require immunofixation of serum and urine in an attempt to demonstrate the presence of a monoclonal light chain. A bone marrow specimen is necessary because 10% of patients will not have a demonstrable monoclonal light chain by immunofixation, and a clone of plasma cells detected in the bone marrow by immunohistochemistry is strong evidence of AL amyloidosis. Immunonephelometric quantitation of serum free light

chains complements immunofixation because it shows remarkable specificity and sensitivity.¹⁴

Biopsy of an affected organ is usually diagnostic, but less invasive alternatives should be preferred first. Biopsies of salivary glands or subcutaneous abdominal fat yield positive results in 80% to 90% of cases. Rectal biopsy is diagnostic in more than 80% of cases, provided the biopsy specimen contains submucosal vessels in which early deposits are located. Bone marrow biopsy specimens should be stained with Congo red for the presence of amyloid, and involvement of the bone marrow (observed in about 50% of patients) is strongly suggestive of the AL type. Evaluation of adequate specimens in experienced laboratories is necessary to maintain high diagnostic sensitivity and specificity.

It is not always easy to be certain that amyloidosis is of the AL type because immunohistochemical staining for immunoglobulin light chains may not be diagnostic (because of loss of epitopes), and the presence of a monoclonal component is strong but not conclusive evidence of the AL type. Caution is required when patients have an intact monoclonal immunoglobulin in the serum without evidence of circulating free light chains in the serum or urine. In those cases, hereditary forms of amyloidosis should be considered because they may produce clinical syndromes indistinguishable from AL and coexist with MGUS.⁴ In cases of doubt, DNA analysis or amyloid fibril sequencing by mass spectrometry may be necessary.

Natural History and Treatment

AL amyloidosis is among the most severe complications of plasma cell proliferative disorders. Median survival is about 10 months. Cardiac involvement responsible for congestive heart failure and arrhythmias account for at least 40% of deaths.

Therapy is aimed at annihilation of the plasma cell clone. All patients with AL amyloidosis deserve a trial of chemotherapy because of the improved survival of responders. In the responders, gradual regression of AL amyloid deposits is possible. However, the results of chemotherapy in AL amyloidosis are difficult to document because there is no easy way to measure amyloid load. Resolution of the nephrotic syndrome does not necessarily reflect loss of amyloid deposits, which can progress even with improved clinical and laboratory findings. Scintigraphy after the injection of [¹²⁵I]-SAP component may be helpful for monitoring the extent of systemic amyloidosis, but this technique is available in a few centers only. The definition of a response in amyloidosis should be hematologic and organ based. A complete hematologic response is defined by negativity of serum and urine for a monoclonal protein by immunofixation, normal free light-chain ratio by the serum free light-chain assay,¹⁷ and less than 5% plasma cells in the bone marrow. There are consensus criteria for organ response and organ disease progression.¹⁸

Until 15 years ago, the only treatment of AL amyloidosis was melphalan with prednisone administered orally in repeated cycles during many months. This treatment had a modest impact on survival because of its delayed action and low rate of hematologic remission.¹⁹ A more aggressive approach consisting of high-dose melphalan (HDM) administered in myeloablative doses (140 to 200 mg/m²) followed by autologous stem cell transplantation (ASCT) started in the mid-1990s, with complete hematologic response and significant functional improvement in a substantial proportion of highly selected patients.²⁰⁻²³ However, treatment-related mortality was consistently higher than in patients treated with ASCT for multiple myeloma or other malignant neoplasms. An alternative to HDM/ASCT consists of

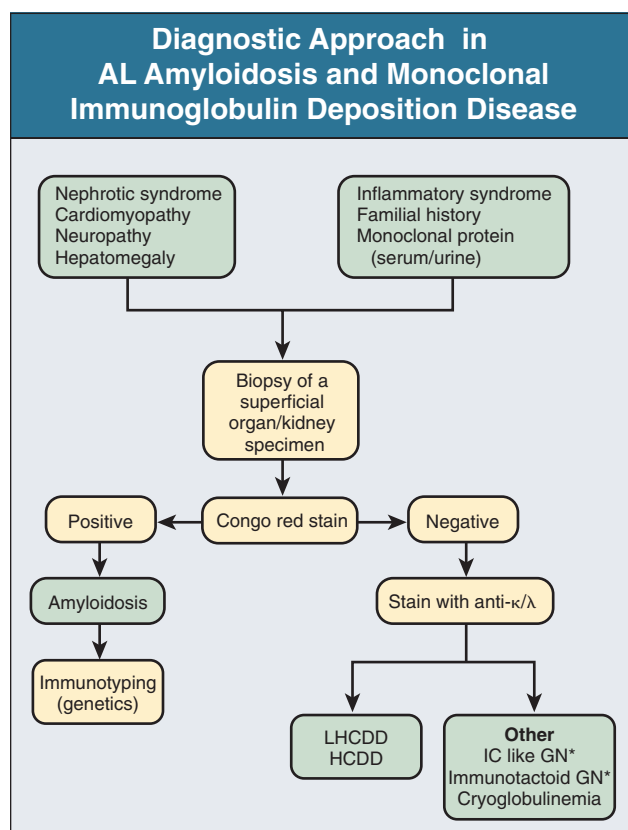

Figure 26.8 Algorithm of diagnostic procedures in light chain (AL) amyloidosis and monoclonal immunoglobulin deposition disease (MIDD). *No extrarenal manifestation. GN, glomerulonephritis; IC, immune complex; HCDD, heavy-chain deposition disease; LHCDD, light- and heavy-chain deposition disease.

treatment with oral melphalan (10 mg/m²/day) together with dexamethasone administered at a high dosage (40 mg/day) in 4-day cycles each month (M/Dex). Early reports of M/Dex treatment described rapid eradication of light-chain production and rapid reduction in N-terminal brain natriuretic peptide.²⁴

A recent trial randomly assigned 100 AL amyloidosis patients to HDM/ASCT or M/Dex.²⁵ Among the 65 patients for whom hematologic response could be evaluated, there was no significant difference in complete response, with 32% of those treated with M/Dex and 41% with HDM/ASCT responding. In an intention-to-treat analysis, median survival was 56.9 months in the M/Dex group compared with 22.2 months in the HDM/ASCT group ($P = .04$). The study investigators concluded that HDM/ASCT is not superior to M/Dex. Problems of the trial included that (1) only 37 of the patients who were randomly assigned to HDM/ASCT actually underwent the treatment and (2) treatment-related mortality in the HDM group (24%) was higher than that reported in single-center studies from amyloidosis referral centers (4% to 14%).²⁶ The high mortality was likely due to enrollment of patients who had severe organ dysfunction and would not be eligible for HDM/ASCT at many referral centers. However, a subset analysis of patients with low risk for an adverse outcome of intensive treatment also showed similar survival at 3 years of 80% in the M/Dex group and 58% in the HDM/ASCT group ($P = 0.13$). Furthermore, patients who survived for at least 6 months after randomization and who received their assigned treatment exhibited similar (20% to 30%) mortality rates.

On the basis of these findings, the following recommendations are proposed: (1) patients with severe organ dysfunction should receive M/Dex as first-line treatment; (2) patients with less severe disease are eligible for M/Dex or HDM/ASCT, still considered the reference treatment in experienced centers in the United States. Patients should be carefully monitored by assessment of free light chains. In those who do not show hematologic responses after 3 to 6 months (>50% decrease of free monoclonal light chain), treatment should be changed to alternatives such as lenalidomide- (or thalidomide-) or bortezomib-based regimens.

Dialysis and Transplantation

Most studies of the clinical course and outcome of dialysis patients include both AL and AA amyloidosis. The patient's survival rate is about 70% at 1 year and decreases to 30% to 44% at 5 to 6 years. Median survival is shorter in patients with AL amyloidosis (26 months) than with AA amyloidosis; sepsis and cardiac deaths are the main causes of mortality.²⁷

Cardiac amyloid is the most important predictor of mortality in dialysis patients with AL amyloidosis.^{27,28} The management of patients with AL amyloid on hemodialysis (HD) is often complicated by persistent hypotension, gastrointestinal hemorrhage, chronic diarrhea, and difficulties in the creation and maintenance of vascular access. It has therefore been suggested that peritoneal dialysis (PD) could have several advantages over HD in the management of end-stage renal amyloidosis, including avoidance of vascular access and deleterious effects on blood pressure; but PD may induce protein loss in the dialysate and thus enhance malnutrition. However, the survival rate of AL and AA amyloidosis patients treated with PD is similar to that of patients on HD.

Renal transplantation is limited by the severity of heart involvement and the recurrence of deposits in the transplanted kidney. There are a few cases and small series reported in the literature of renal transplantation in AL amyloidosis. Renal transplantation may be considered in patients whose underlying

clonal plasma cell disease has remitted after chemotherapy. Heart transplantation can also be envisaged in specific cases as a tandem with HDM/ASCT or after remission.

AA Amyloidosis

Epidemiology

AA amyloidosis develops in 5% of patients with sustained elevation of serum amyloid A protein (SAA). Patients at risk are those with a long duration of chronic inflammatory disease (median, 17 years),²⁹ high magnitude of acute-phase SAA response, homozygosity for SAA1 isotype, familial Mediterranean fever (FMF) trait (heterozygosity for variant pyrin), and family history of AA amyloidosis.

An important epidemiologic aspect of AA amyloidosis is the changing spectrum of underlying diseases. Pyogenic and granulomatous infections, especially tuberculosis, account for far fewer cases today (15%) than previously.²⁹ Thus, antibiotic treatment efficiently prevents AA amyloidosis by suppressing its cause. In contrast, the prevalence of chronic inflammatory arthritis has increased dramatically (60%).²⁹ AA amyloidosis in patients with Hodgkin's disease has virtually disappeared with more efficient treatment of the hematologic disease. Hereditary AA amyloidoses associated with familial recurrent fever syndromes account for an increasing proportion of cases, about 10% in recent series.

Clinical Manifestations

Clinical manifestations of AA amyloidosis are shown in [Figure 26.9](#).²⁹ The main target organ is the kidney, which is affected in almost all patients with AA amyloidosis. Presentation may be acute with nephrotic syndrome or very insidious. Proteinuria is absent in about 5% of cases. Gastrointestinal disturbances (including diarrhea, constipation, and malabsorption) and hepatosplenomegaly are the next most common manifestations. In contrast with AL amyloidosis, congestive heart failure, peripheral neuropathy, macroglossia, and carpal tunnel syndrome occur infrequently.

Diagnosis

A systematic search for amyloidosis is recommended in patients with active, long-lasting inflammatory arthritis, even in the absence of proteinuria and chronic kidney disease (CKD). Although findings on kidney biopsy are positive in almost 100% of symptomatic patients, less invasive biopsy procedures should be attempted first. Biopsies of accessory salivary glands, abdominal fat, and rectal mucosa yield positive results in 50% to 80% of patients. Immunohistochemical staining using antibodies to SAA is required to confirm that Congo red–positive amyloid deposits are of the AA type. SAP scintigraphy shows that bones are not affected (contrary to AL amyloidosis).

Natural History and Treatment

Survival time of patients with AA amyloidosis is 133 months, much longer than with AL amyloidosis.²⁹ Main causes of death are infections and dialysis-related complications but not cardiac complications. Amyloid load and clinical outcome relate to circulating concentrations of SAA.²⁹ The relative risk of death among patients with an SAA concentration below 4 mg/l is almost 18 times lower than among patients with an SAA concentration of 155 mg/l or greater. Even a very modest elevation in the SAA concentration of 4 to 9 mg/l is associated with a risk of death increased by a factor of 4. These data emphasize the importance of vigorous treatment of the underlying

inflammatory disease. SAA (preferable to C-reactive protein) levels should be monitored monthly and maintained at a target value of less than 4 mg/l.²⁹

Amyloid deposits regress in 60% of patients who have a median SAA concentration below 10 mg/l, and survival among these patients is superior to survival when amyloid deposits do not regress. Other factors associated with increased mortality are older age and end-stage renal disease (ESRD).

Eprodinate, a member of a new class of compounds interfering with interactions between amyloidogenic proteins and GAGs and thereby inhibiting polymerization of amyloid fibrils, slowed the decline of renal function in patients with AA amyloidosis.³⁰ However, eprodinate had no beneficial effect on proteinuria, ESRD, amyloid content of abdominal fat, or risk of death. Although eprodinate may be a promising treatment option for AA amyloidosis, emphasis should remain on treatment of the underlying inflammatory disorder.

Most described patients receiving renal transplantation in AA amyloidosis are those with rheumatic diseases. Amyloid deposits recur in about 10% of the grafts. Infection is the main cause of early death.

Familial Mediterranean Fever and Other Hereditary Recurrent Fever Syndromes

FMF represents a particular type of AA amyloidosis and the most frequent cause of familial amyloidosis. Colchicine has proved to be efficient in its prevention and treatment. FMF is usually transmitted as an autosomal recessive disorder and occurs most commonly in Sephardic Jews and Armenians. It is caused by mutations

of the gene (*MEFV*) encoding a protein called pyrin or marennin.³¹ Clinically, there are two independent phenotypes. In the first, brief, episodic, febrile attacks of peritonitis, pleuritis, or synovitis occur in childhood or adolescence and precede the renal manifestations. In the second, renal symptoms precede and may be the only manifestation of the disease for a long time. The attacks are accompanied by dramatic elevations of acute-phase reactants, including SAA. Amyloid deposits are responsible for severe renal lesions with prominent glomerular involvement, leading to ESRD at a young age, and for early deaths. Colchicine can prevent the development of proteinuria, may occasionally reverse the nephrotic syndrome, and may prevent the glomerular filtration rate (GFR) decline in patients with non-nephrotic proteinuria. It is less effective in preventing progression in patients with nephrotic syndrome or renal impairment. The minimal daily dose of colchicine for prevention of amyloidosis is 1 mg, and patients with clinical evidence of amyloidotic kidney disease should receive daily doses of 1.5 to 2 mg. However, about 10% of patients are unresponsive to colchicine. Interleukin-1 receptor antagonists are second-line agents. In patients with intolerance of colchicine, the drug should be stopped, then reintroduced at lower doses.

The recent identification of genes responsible for syndromes of periodic fever with amyloidosis has opened the way to a molecular diagnosis of hereditary AA amyloidosis. These syndromes include the tumor necrosis factor receptor-associated periodic syndrome, the Muckle-Wells syndrome, and the familial cold autoinflammatory syndrome. Only a few cases of systemic AA amyloidosis have been reported in the hyperimmunoglobulinemia D with periodic fever syndrome.

MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASE

History and Definition

It was known from the late 1950s that nonamyloidotic forms of glomerular disease “resembling the lesion of diabetic glomerulosclerosis” could occur in multiple myeloma. Subsequently, monoclonal light chains were detected in these lesions.³²

In clinical and pathologic terms, light-chain, light- and heavy-chain, and heavy-chain deposition disease (LCDD, LHCDD, and HCDD, respectively) are similar and may therefore be referred to as MIDD. They differ from amyloidosis in that the deposits lack affinity for Congo red and do not have a fibrillar organization. The distinction also relates to different pathophysiology of amyloid, which implicates one-dimensional elongation of a pseudocrystalline structure, and MIDD, which rather involves a one-step precipitation of immunoglobulin chains.

Epidemiology

LCDD is found in 5% of myeloma patients at autopsy, whereas the prevalence of AL amyloidosis is about 11%. LCDD and HCDD may occur in a wide range of ages (28 to 94 years) with a male preponderance (Fig. 26.10). More than 20 patients with HCDD have been described so far, but the disease is most likely underdiagnosed.

Pathogenesis

Light-chain deposition may require light chains with distinct properties that favor deposition in tissues. Various properties

of light-chain variable domains may contribute to MIDD pathogenesis³³:

1. Restricted usage of three κ germline genes, with an apparent overrepresentation of the rare $V_{\kappa IV}$ variability subgroup.
2. Size abnormalities of light chains, present in one third of patients.
3. Unusual amino acid substitutions in LCDD light chains may modify the light-chain conformation or be responsible for hydrophobic interactions between V domains or between V domains and extracellular matrix proteins.
4. When pathogenic light chains were absent in serum and urine, they seemed to be *N*-glycosylated, suggesting that glycosylation increases their propensity to precipitate in tissues. However, as in AL amyloidosis, extrinsic conditions may also contribute to aggregation of the light chain. The same light chain can form granular aggregates or amyloid fibrils, depending on the environment, and different partially folded intermediates of the light chain may be responsible for amorphous or fibrillar aggregation pathways.³⁴

HCDD may also be associated with unique heavy chains. A deletion of the first constant domain C_{H1} was found in deposited or circulating heavy chains in patients with γ -HCDD.^{33,35} In the blood, the deleted heavy chain either was associated with light chains or circulated in small amounts as a free unassembled subunit.³⁶ It is likely that the C_{H1} deletion facilitates the secretion of free heavy chains that are rapidly cleared from the circulation by organ deposition. The variable V_H domain also is likely to be required for tissue precipitation.

A striking feature of LCDD and HCDD is extracellular matrix accumulation. Nodules are made of normal matrix constituents. In cultured mesangial cells, LCDD light chains enhance the production of tenascin-C and of profibrotic cytokines, such as transforming growth factor β and platelet-derived growth factor.³⁷

Clinical Manifestations

MIDD is a systemic disease with immunoglobulin chain deposition in a variety of organs leading to various clinical manifestations, but visceral immunoglobulin chain deposits may be totally asymptomatic and found only at autopsy.³³

Renal Manifestations

Renal involvement is a constant feature of MIDD, and renal symptoms, mostly proteinuria and CKD, often dominate the clinical presentation (see Fig. 26.10).^{33,35} In 18% to 53% of LCDD patients, albuminuria is associated with the nephrotic syndrome. However, in about one fourth, it is less than 1 g/day, and these patients exhibit mainly a tubulointerstitial syndrome. Albuminuria is not correlated with the presence of nodular glomerulosclerosis, at least initially, and may occur in the absence of significant light microscopic glomerular lesions. Hematuria is more frequent than one would expect for a nephropathy in which cell proliferation is usually modest.

The high prevalence, early appearance, and severity of CKD are other salient features of LCDD. In most cases, GFR declines rapidly, which is a main reason for referral. CKD occurs with comparable frequency in patients with either low or heavy protein excretion and may present in the form of a subacute tubulointerstitial nephritis or a rapidly progressive glomerulonephritis (RPGN), respectively. The prevalence of hypertension is variable, but it must be interpreted according to associated medical history. Renal features of patients with HCDD are basically similar to those seen in LCDD and LHCDD, with a higher prevalence of hypertension and hematuria; extrarenal manifestations are less frequent (see Fig. 26.10).

Extrarenal Manifestations

Liver and cardiac involvement occurs in about 25% of patients with LCDD and LHCDD. Liver deposits are constant. They are either discrete and confined to the sinusoids and basement membranes of biliary ductules without associated parenchymal lesions or massive with marked dilation and multiple ruptures of sinusoids, resembling peliosis. Hepatomegaly with mild alterations of liver function test results is the most common symptom, but patients may also develop life-threatening hepatic insufficiency and portal hypertension.

Cardiac involvement is also frequent and may be responsible for cardiomegaly and severe heart failure. Arrhythmias, conduction disturbances, and congestive heart failure are seen. Echocardiography and catheterization may reveal diastolic dysfunction and reduction in myocardial compliance similar to that found in cardiac amyloid.

Deposits may also occur along the nerve fibers and in the choroid plexus as well as in the lymph nodes, bone marrow, spleen, pancreas, thyroid gland, submandibular glands, adrenal glands, gastrointestinal tract, abdominal vessels, lungs, and skin. They may be responsible for peripheral neuropathy (20% of the reported cases), gastrointestinal disturbances, pulmonary nodules, amyloid-like arthropathy, and sicca syndrome. Extrarenal deposits are less common in patients with HCDD.

Hematologic Findings

Myeloma is diagnosed in about 50% of the patients with LCDD or LHCDD and in about 25% of those with HCDD. MIDD, like AL amyloidosis, is often the presenting disease that leads to the discovery of myeloma at an early stage. MIDD may occasionally complicate Waldenström's macroglobulinemia, chronic

lymphocytic leukemia, and nodal marginal zone lymphoma. It often occurs in the absence of a detectable malignant process, even after prolonged (>10 years) follow-up. A monoclonal bone marrow plasma cell population is then easily detectable by immunohistologic examination.

Pathology

Light Microscopy

MIDD is not only a glomerular disease, and tubular lesions may be more conspicuous than the glomerular damage. Tubular lesions are characterized by the deposition of a refractile, eosinophilic, periodic acid–Schiff (PAS)–positive, ribbon-like material along the outer part of the tubular basement membrane. The deposits predominate around the distal tubules, the loops of Henle, and, in some instances, the collecting ducts, whose epithelium is flattened and atrophied. Typical myeloma casts are only occasionally seen in pure forms of MIDD. In advanced stages, a marked interstitial fibrosis including refractile deposits is frequently associated with tubular lesions.

Glomerular lesions are heterogeneous. Nodular glomerulosclerosis is the most characteristic (Fig. 26.11A); it is found in 30% to 100% of patients with LCDD. Expansion of the mesangial matrix with nodular glomerulosclerosis characterizes HCDD. Mesangial nodules are composed of PAS-positive, membrane-like material and are often accompanied by mild mesangial hypercellularity. Lesions resemble diabetic nodular glomerulosclerosis. Distinctive characteristics include the following: the distribution of the nodules is fairly regular in a given glomerulus; the nodules are often poorly argyrophilic; and exudative lesions such as fibrin caps and extensive hyalinosis of the efferent arterioles are not observed. In occasional cases with prominent endocapillary cellularity and mesangial interposition, the glomerular features mimic membranoproliferative glomerulonephritis (MPGN). Milder forms of LCDD show increased mesangial matrix or cells and a modest basement membrane thickening, with abnormal brightness and rigidity. Glomerular lesions may be detectable only by immunostaining or ultrastructural examination in early stages or if they are induced by light chains with a weak pathogenic potential.

Arteries, arterioles, and peritubular capillaries all may contain PAS-positive deposits in close contact with their basement membranes. Deposits do not show the staining characteristics of amyloid, but Congo red–positive amyloid deposits co-occur in approximately 10% of patients.³⁵

Immunohistology

Immunohistology is central in the diagnosis of the various forms of MIDD. A criterion required for the diagnosis of MIDD is monotypic light-chain (mostly κ ; Fig. 26.11B) or heavy-chain fixation along tubular basement membranes. The tubular deposits stain strongly (see Fig. 26.11B) and predominate along the loops of Henle and the distal tubules, but they also often are detected along the proximal tubules. In contrast, glomerular immunohistology patterns display marked heterogeneity. In patients with nodular glomerulosclerosis, deposits of monotypic immunoglobulin chains are usually found along the peripheral GBM and, to a lesser extent, in the nodules themselves (Fig. 26.11B). Glomerular staining is typically weaker than that observed along the tubular basement membranes. This may not relate to the actual amount of deposited material because glomerular immunohistology may be negative despite prominent granular glomerular deposits observed by electron microscopy. Local modifications of deposited light chains thus might change their antigenicity. In patients without nodular lesions, glomerular staining occurs along the basement membrane and less frequently in the mesangium. A linear staining usually decorates Bowman's capsule. Deposits are frequent in vascular walls and interstitium.

In patients with HCDD, immunohistology with anti-light-chain antibodies is negative despite typical nodular glomerulosclerosis. Monotypic deposits of γ , α , or μ heavy chains may be identified. Any γ subclass may be observed. Analysis of the kidney biopsy specimen with monoclonal antibodies specific for the constant domains of the γ heavy chain allowed identification of a deletion of the C_{H1} domain in all tested cases. In most cases of HCDD, especially when a $\gamma 1$ or $\gamma 3$ chain is involved, complement components including C1 could be demonstrated in a granular or pseudolinear pattern. Complement deposits were often associated with signs of complement activation in serum.³⁸

Electron Microscopy

The most characteristic ultrastructural features are finely to coarsely granular electron-dense deposits along the outer (interstitial) aspect of the tubular basement membranes. In the glomerulus, they predominate in a subendothelial position along the GBM and are located mainly along and in the lamina rara interna (Fig. 26.11C). They can also be found in mesangial nodules, Bowman's capsule, and the wall of small arteries between the myocytes. Nonamyloid fibrils have been reported in a few patients with LCDD or HCDD.

Diagnosis

The diagnosis of MIDD must be suspected in any patient with the nephrotic syndrome or rapidly progressive tubulointerstitial nephritis or with echocardiographic findings indicating diastolic dysfunction and the presence of a monoclonal immunoglobulin component in the serum or the urine (see Fig 26.8). The same combination is also seen in AL amyloidosis, but AL amyloidosis is more often associated with the λ light-chain isotype. Because sensitive techniques including immunofixation fail to identify a monoclonal immunoglobulin component in 10% to 20% of patients with LCDD or LHCDD and about 40% of patients with HCDD (see Fig. 26.10), renal biopsy plays an essential role in the diagnosis of MIDD and the associated dysproteinemia.

The definitive diagnosis is made by the immunohistologic analysis of tissue from an affected organ, in most cases the kidney, with use of a panel of immunoglobulin chain-specific antibodies, including anti- κ and anti- λ light-chain antibodies to stain the non-congophilic deposits. When the biopsy specimen stains for a single heavy-chain isotype and does not stain for light-chain isotypes, the diagnosis of HCDD should be suspected.

The diagnosis of the plasma cell dyscrasia relies on bone marrow aspiration and bone marrow biopsy with cell morphologic evaluation and, if necessary, immunophenotyping with anti- κ and anti- λ antisera to demonstrate monoclonality.

Outcome

The outcome of MIDD remains uncertain, mainly because extrarenal deposits of light chains can be totally asymptomatic or cause severe organ damage leading to death. Survival from onset of symptoms varies from 1 month to 10 years. In the largest series of LCDD patients,³⁹ 36 of the 63 patients reached uremia, 37 of those patients died during follow-up, and patient survival was 66% at 1 year and 31% at 8 years, although most were treated by chemotherapy. By multivariate analysis, the only variables independently associated with renal survival were age and degree of chronic kidney disease (CKD) at presentation³⁹ or the time of renal biopsy.³⁵ Those variables independently associated with a worse patient survival were age, initial creatinine level, associated multiple myeloma, and extrarenal light-chain deposition.^{33,37} Survival of the patients treated with dialysis was not different from that of the patients not reaching ESRD. Renal and patient survivals were significantly better in patients with pure MIDD (mean, 22 and 54 months, respectively) compared with those who presented with cast nephropathy (mean, 4 and 22 months, respectively).³⁵

Treatment

As in AL amyloidosis, treatment should be aimed at reducing immunoglobulin production. Clearance of the light-chain deposits has been demonstrated in a few patients after intensive chemotherapy with syngeneic bone marrow transplantation or blood stem cell autografting. Nodular mesangial lesions and light-chain deposits are reversible, also disappearing after long-term chemotherapy.

In a retrospective study of 11 LHCDD patients (younger than 65 years) treated by high-dose therapy with the support of autologous blood stem cell transplantation, no treatment-related death occurred.⁴⁰ A decrease in the monoclonal immunoglobulin level was observed in eight patients, with complete disappearance

from serum and urine in six cases. Clinical improvement was observed in six patients, and histologic regression was documented in cardiac, hepatic, and skin biopsy specimens. These results were confirmed in two small North American series.^{41,42} Reversal of dialysis dependency and sustained improvement in renal function were also occasionally noted. Whether high-dose chemotherapy with blood stem cell transplantation provides benefits compared with conventional chemotherapy including high-dose dexamethasone, with or without bortezomib, remains to be established.

As with AL amyloidosis, monitoring of light-chain production should rely on serum free light-chain assay, particularly when a blood or urine monoclonal component cannot be detected by conventional methods.

Kidney transplantation in a few patients with MIDD usually led to recurrence of the disease and should therefore not be performed in LCDD patients unless measures have been taken to reduce light-chain production.⁴³

Renal Diseases Associated with Monoclonal Immunoglobulin Deposition Disease

Myeloma Cast Nephropathy

The association of monoclonal light chain deposits, mostly along renal tubular basement membranes, with typical myeloma cast nephropathy is more frequent than reported initially. It was found in 11 of 34 patients with MIDD.³⁵ Nodular glomerulosclerosis is, however, infrequent (<10%), and some ribbon-like tubular basement membranes are seen in less than half of the patients. In addition, one third of the patients do not have granular dense deposits on electron microscopy.

AL Amyloidosis

Amyloid deposits are found in one or more organs in about 7% of LCDD patients. Because amyloid deposits are focal, their true incidence may be markedly underestimated. Although this association may result from peculiar light chains endowed with intrinsic properties that make them prone to form both fibrillar and nonfibrillar deposits, depending on the environment,³⁴ one cannot exclude the possibility that the coexisting diseases are induced by different variant clones.

NONAMYLOID FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Definition

Fibrillary and immunotactoid glomerulopathies are characterized, respectively, by fibrillar and microtubular deposits in the mesangium and the glomerular capillary loops (Fig. 26.12). These deposits do not have an amyloid-like cross- β structure and are readily distinguishable from amyloid by the larger thickness of fibrils and lack of Congo red staining. Whether fibrillary and immunotactoid glomerulopathies are totally distinct entities is debated. Some use immunotactoid glomerulopathy as a unifying term for glomerular deposition of either amyloid-like fibrils (12 to 22 nm) or larger microtubules (>30 nm) in patients for whom an associated systemic disease, including cryoglobulinemia and lymphoproliferative disorders, has been excluded.⁴⁴ For others, the distinction between nonamyloid fibrillary and immunotactoid glomerulopathy may be of great clinical and pathophysiologic interest in the context of plasma cell dyscrasias (see Fig. 26.12).⁴⁵⁻⁴⁸

Epidemiology

The incidence of glomerulopathy with nonamyloid deposition of fibrillar or microtubular material in a nontransplant adult biopsy population is estimated at around 1%. It is most likely underestimated because of the insufficient attention given to atypical reactions with histochemical amyloid stains and the frequent lack of immuno-ultrastructural studies.

Clinical Manifestations

The characteristics of fibrillary and immunotactoid glomerulopathies are described in Figure 26.12 in comparison to AL amyloidosis. Patients with immunotactoid and fibrillary glomerulopathies have a mean age of 55 to 60 years (extreme: 19 to 86 years). They usually present with the nephrotic syndrome, microscopic hematuria, and mild to severe CKD. In most recent

series,^{47,48} there was no significant difference between immunotactoid and fibrillary glomerulopathy patients in serum creatinine level, incidence of nephrotic syndrome, microscopic hematuria, hypertension, and CKD. Extrarenal manifestations are uncommon and may involve the lung, skin, and peripheral nervous system.

Pathology

Immunotactoid Glomerulopathy

Renal biopsy shows MN (often associated with segmental mesangial proliferation; Fig. 26.13) or lobular MPGN. Granular deposits of IgG and C3 are observed along capillary basement membranes and in mesangial areas. In a series of 23 patients in which diagnosis was based on ultrastructural appearance of the deposits, IgG deposits were monotypic in 13 of 14 patients with immunotactoid glomerulopathy (κ, seven cases; λ, six cases) and

Immunologic and Clinical Characteristics of Fibrillary and Immunotactoid Glomerulopathies			
Characteristics	Amyloidosis (AL Type)	Fibrillary Glomerulopathy	Immunotactoid Glomerulopathy
Congo red staining	Yes	No	No
Composition	Fibrils	Fibrils	Microtubules
Fibril or microtubule size	8–15 nm	12–22 nm	>30 nm*
Organization in tissues	Random (β-pleated sheet)	Random	Parallel arrays
Immunoglobulin deposition	Monoclonal LC (mostly λ)	Usually polyclonal (mostly IgG4), occasionally monoclonal (IgG1, IgG4)	Usually monoclonal (IgGκ or IgGλ)
Glomerular lesions	Deposits spreading from the mesangium	MPGN, CGN, MP	Atypical MN, MPGN
Renal presentation	Severe NS, absence of hypertension and hematuria	NS with hematuria, hypertension; RPGN	NS with microhematuria and hypertension
Extrarenal manifestations (fibrillar deposits)	Systemic deposition disease	Pulmonary hemorrhage	Microtubular inclusions in leukemic lymphocytes
Association with LPD	Yes (myeloma)	Uncommon	Common (CLL, NHL, MGUS)
Treatment	Melphalan + dexamethasone; intensive therapy with blood stem cell autograft	Corticosteroids ± cyclophosphamide (crescentic GN)	Treatment of the associated LPD

in only one of nine patients with fibrillary glomerulopathy.⁴⁷ A circulating monoclonal immunoglobulin was detected in only six of the 14 patients with immunotactoid glomerulopathy. On electron microscopy, the distinguishing morphologic features of immunotactoid glomerulopathy are organized deposits of large, thick-walled microtubules (typically >30 nm in diameter), at times arranged in parallel arrays (Fig. 26.13C).

Of 14 patients with immunotactoid glomerulopathy,⁴⁷ six had chronic lymphocytic leukemia, one had a small lymphocytic B-cell lymphoma, and three had MGUS. Intracytoplasmic crystal-like immunoglobulin inclusions were found in four patients with chronic lymphocytic leukemia and in the lymphoma patient.⁴⁷ They showed the same microtubular organization and contained the same IgG subclass and light-chain isotype as renal deposits.

Fibrillary Glomerulopathy

Mesangial proliferation and aspects of MPGN are predominantly reported in series of fibrillary glomerulopathy. Glomerular crescents are present in about 30% of the biopsy specimens. Immunofluorescence studies mainly show IgG deposits of the $\gamma 4$ isotype with a predominant mesangial localization. Monotypic deposits containing mostly IgG κ are detected in no more than 15% of patients. On electron microscopy, fibrils are randomly arranged, and their diameter varies between 12 and 22 nm. The fibril size alone is not sufficient to distinguish nonamyloidotic fibrillary GN from amyloid.⁴⁷

Diagnosis

Diagnosis of immunotactoid and fibrillary glomerulopathies relies on electron microscopy, which must be performed in patients with atypical MN or MPGN as well as in those with monotypic deposits in glomeruli. Renal biopsy specimens from such patients with glomerular disease should be routinely examined with anti- κ and anti- λ light-chain antibodies. In patients with immunotactoid glomerulopathy, lymphoproliferative disease should be searched for. Association of immunotactoid and fibrillary glomerulopathy with hepatitis C or human immunodeficiency virus infection has also been reported.

Outcome and Treatment

Patients with fibrillary glomerulopathy usually respond poorly to corticosteroids and cytotoxic drugs, with an incidence of ESRD of 50%. Preliminary reports suggest that they may respond to rituximab.⁴⁹ By contrast, in patients with immunotactoid glomerulopathy, corticosteroids and chemotherapy were associated with partial or complete remission of the nephrotic syndrome in most cases, with a parallel improvement of the hematologic parameters.⁴⁷ Patient survival was found to be similar in both types of glomerulopathies, although the incidence of CKD and ESRD tended to be lower in the immunotactoid glomerulopathy group.⁴⁷ Renal transplantation has been performed in a few patients. Disease recurred in several, especially in those with a persistent monoclonal gammopathy.⁵⁰

GLOMERULAR LESIONS ASSOCIATED WITH WALDENSTRÖM'S MACROGLOBULINEMIA

Symptomatic renal disease is much less common than in multiple myeloma. GN with intracapillary thrombi of aggregated IgM

(intracapillary monoclonal deposit disease) is the most frequent renal morphologic finding, but it has become rare, probably because of increased efficacy of chemotherapy. This entity may also occur with other IgM-secreting monoclonal proliferations.⁵¹ It is associated with variable degrees of proteinuria and altered renal function. It is characterized by PAS-positive, Congo red-negative intracapillary deposits, sometimes voluminous enough to occlude capillary lumina. By immunohistology, thrombi and deposits stain with anti- μ and with anti- κ . The deposits are electron dense and granular without any microtubular organization.⁴⁹ Some of these patients have strong activation of the classical complement pathway with or without cryoglobulinemia. Other patients have MPGN with a bright μ and κ staining along the glomerular capillaries, without cryoglobulinemia. Renal manifestations usually improve under chemotherapy. Renal amyloidosis (mostly AL) is uncommon but should be suspected in patients presenting with massive proteinuria. Because renal biopsy may be hazardous in patients with Waldenström's macroglobulinemia, who frequently have increased bleeding time, it is wise to search for amyloid deposits first by a less invasive tissue biopsy. Hematopoietic stem cell transplantation and purine analogues may represent the most effective therapies.¹⁶

OTHER TYPES OF GLOMERULONEPHRITIS

In some patients, glomerular deposition of monoclonal IgG can produce a proliferative GN that mimics immune complex GN on light and electron microscopy.⁵² Proper recognition of this entity requires confirmation of monoclonality by immunostaining for the γ heavy chain subclasses. Tissue fixation of complement was observed in 90% of cases, and 40% of patients had hypocomplementemia. Clinical presentation included CKD in 80%, proteinuria in 100%, nephrotic syndrome in 44%, and microhematuria in 60%. A monoclonal serum protein with the same heavy- and light-chain isotype as that of the glomerular deposits was identified in 50% of cases. No patient had overt myeloma or lymphoma at presentation or during the course of follow-up.

Other Glomerular Disorders and Antiphospholipid Syndrome

Richard J. Glassock

This chapter provides a description of several glomerular and vascular diseases, not necessarily related to each other. Each disorder must be recognized and differentiated from other more common glomerular disorders to estimate the prognosis, to determine whether a familial disorder is present, to plan appropriate therapy, or to determine the risk of a recurrence in the transplanted kidney.

MESANGIAL PROLIFERATIVE GLOMERULONEPHRITIS WITHOUT IgA DEPOSITS

Mesangial proliferative glomerulonephritis (MesPGN) encompasses a heterogeneous collection of disorders of diverse and largely unknown etiology and pathogenesis that have in common a histologic pattern by light microscopy of glomerular injury characterized by mesangial proliferation (Fig. 27.1).¹⁻³ MesPGN is noted for a diffuse and global increase in mesangial cells, often accompanied by an increase in mesangial matrix. Other cells (e.g., monocytes) may also contribute to the hypercellularity.

For the purpose of this discussion, other forms of cellular proliferation that occur within the mesangial zones but are more focally and segmentally distributed are not included. These focal and segmental forms of proliferative glomerulonephritis (GN) (often accompanied by areas of segmental necrosis of the glomerular tufts and very localized crescents) may be a part of the evolutionary stages of an initially pure MesPGN, but they very often signify the presence of systemic disease processes, including systemic lupus erythematosus (SLE), Henoch-Schönlein purpura and IgA nephropathy, infective endocarditis, microscopic polyangiitis, Wegener's granulomatosis, Goodpasture's disease, rheumatoid vasculitis, and mixed connective tissue disease. On occasion, a lesion of focal and segmental proliferative GN is discovered in the absence of any recognizable multisystem disease process and in the absence of IgA deposits (i.e., idiopathic focal and segmental proliferative GN). Such patients have a clinical presentation, course, and response to treatment that are similar to those described for pure MesPGN, but they are not discussed further in this section.

In "pure" MesPGN, the peripheral capillary walls are thin and delicate without obvious deposits, reduplication, focal disruptions, or cellular necrosis. The visceral and parietal epithelial cells, although occasionally enlarged, have not undergone proliferation. Crescents and segmental sclerosis should be absent in the pure disease. In addition, large deposits staining with

periodic acid-Schiff or fuchsin in the mesangium should be absent, as they suggest IgA nephropathy (see Chapter 22) or lupus nephritis (see Chapter 25). The tubulointerstitium and vasculature are usually normal, unless reduced renal function or hypertension is present or the patient is of advanced age.

On immunofluorescence microscopy, a wide variety of patterns are observed (Fig. 27.2). Most commonly, diffuse and global IgM and C3 deposits are found scattered diffusely throughout the mesangium in a granular pattern (so-called IgM nephropathy), but isolated C3, C1q, or even IgG deposits may also be seen.⁴ If IgA is the predominant immunoglobulin deposited, the diagnosis is IgA nephropathy. Not uncommonly, no immunoglobulin deposits are found at all.

On electron microscopy, the number of mesangial cells is increased, with an occasional infiltrating monocyte or polymorphonuclear leukocyte. The amount of mesangial matrix is commonly diffusely increased. Electron-dense deposits within the mesangium can be seen in many cases, particularly those with immunoglobulin (IgG, IgM, or IgA) deposits on immunofluorescence microscopy. Very large mesangial or paramesangial electron-dense deposits suggest IgA nephropathy even if immunofluorescence microscopy is not available. Subendothelial and subepithelial deposits are not seen. If present, they suggest a postinfectious etiology or underlying lupus nephritis. Deposits of multiple immunoglobulin classes identified by immunohistology and large numbers of tubuloreticular inclusions on electron microscopy suggest underlying lupus nephritis.

The clinical presentation of MesPGN is varied, although persistent or recurring microscopic or macroscopic hematuria with mild proteinuria is most common. Nephrotic syndrome with heavy proteinuria is a less frequent initial presentation but is seen more frequently in association with diffuse mesangial IgM deposits (IgM nephropathy)² or C1q deposits (C1q nephropathy).^{4,5} Pure MesPGN is a rather uncommon lesion (<5%) in patients diagnosed with idiopathic nephrotic syndrome.^{2,3} Renal function and blood pressure are usually normal, at least initially. Serologic studies are generally unrewarding. Serum C3 and C4 complement components and hemolytic complement activity (CH50) are normal. Assay results for antinuclear antibody (ANA), antineutrophil cytoplasmic autoantibody (ANCA), anti-glomerular basement membrane (anti-GBM) autoantibody, and cryoimmunoglobulins are negative. Nevertheless, these studies should be performed in most patients to exclude known causes. MesPGN can also be a finding in resolving postinfectious (poststreptococcal) GN. Isolated C3 deposits with scanty subendothelial or subepithelial (hump-like) deposits on electron microscopy may be seen in this situation.

Figure 27.1 Pure mesangial proliferative glomerulonephritis (MesPGN). Note the increase in mesangial cellularity, the delicate peripheral capillary walls, and the absence of sclerosis or parietal epithelial cell proliferation. (Hematoxylin-eosin; magnification $\times 410$.) (Modified from reference 1.)

Immunofluorescence Microscopy Patterns in Mesangial Proliferative Glomerulonephritis

Pattern	Associated Disorders
Predominantly mesangial IgA deposits	IgA nephropathy (\pm IgM, C3)
Predominantly mesangial IgG deposits	Often associated with systemic lupus (\pm IgM, C3)
Predominantly mesangial IgM deposits	IgM nephropathy (\pm C3)
Mesangial C1q deposits	C1q nephropathy (\pm IgG, IgM, C3)
Isolated mesangial C3 deposits	Often associated with resolving poststreptococcal GN
Negative for immunoglobulin or complement deposits	Idiopathic MesPGN

Figure 27.2 Immunofluorescence microscopy patterns in mesangial proliferative glomerulonephritis (MesPGN).

IgM Nephropathy

IgM nephropathy² is characterized by diffuse and generalized glomerular deposits of IgM often accompanied by C3. Mesangial electron-dense deposits are also observed. On light microscopy, a picture of pure MesPGN is observed. Patients may present with recurring macroscopic hematuria and proteinuria, the latter in the nephrotic range in as many as 50% of patients. Persisting abnormalities and a poor response to corticosteroids or immunosuppressive therapy are often seen. As many as 50% of patients will eventually progress to typical focal and segmental glomerulosclerosis and, if unresponsive to corticosteroids, will slowly develop chronic kidney disease (CKD) and end-stage renal disease (ESRD). The etiology and pathogenesis are unknown.

C1q Nephropathy

C1q nephropathy is characterized by diffuse deposits of C1q, often accompanied by IgG, IgM, or both.^{4,5} C3 deposits are observed less frequently. These immunopathologic features resemble those seen in lupus nephritis; however, these patients

have none of the clinical features of SLE and do not develop SLE even after prolonged follow-up.⁵ In addition to MesPGN, other morphologic lesions, including focal and segmental glomerulosclerosis, are commonly observed by light microscopy. Nephrotic-range proteinuria, often with hematuria, is observed. Males predominate, and African Americans are commonly affected. Serum C3 components, ANA, and anti-double-stranded DNA antibodies are consistently normal or negative. The response to treatment is poor, and progression to ESRD may occur. The existence of both entities, that is, IgM nephropathy and C1q nephropathy, is disputed by some renal pathologists.

Mesangial Proliferative Glomerulonephritis Associated with Minimal Change Disease

MesPGN may also be a part of the spectrum of minimal change disease (MCD)—focal segmental glomerulosclerosis (FSGS) lesions (see also Chapters 17 to 19). Distinct mesangial hypercellularity superimposed on a lesion of MCD (diffuse foot process effacement seen on electron microscopy) may point to a greater likelihood for corticosteroid unresponsiveness and an eventual evolution to the FSGS lesion.

Natural History of Mesangial Proliferative Glomerulonephritis

The natural history of MesPGN is quite varied, undoubtedly the result of etiologic heterogeneity. In many patients, a benign course ensues, especially if hematuria and scant proteinuria (<1 g/day) are the principal features. Persisting nephrotic syndrome has a less favorable prognosis, and such patients may evolve into FSGS (see Chapter 18) and accompanying progressive CKD.³

Treatment of Mesangial Proliferative Glomerulonephritis

The treatment of pure MesPGN, unaccompanied by other underlying diseases or lesions such as SLE, C1q nephropathy, IgM nephropathy, minimal change lesion, or IgA nephropathy, has not been well defined.^{2,3} No prospective, randomized, controlled trials have been performed because of the uncommon nature of the disorder. As the prognosis for patients with isolated hematuria or hematuria combined with mild proteinuria (<500 mg/day) is generally benign, no treatment other than management of hypertension is needed. For those patients with nephrotic syndrome, with or without impaired renal function, a more aggressive approach is often recommended, especially in the presence of diffuse IgM deposits, because many such patients will eventually progress to FSGS. Even in the absence of controlled trials, an initial course of corticosteroid therapy may be justified in most patients with nephrotic-range proteinuria (e.g., prednisone 60 mg/day or 120 mg every other day for 2 to 3 months followed by lowered doses, on an alternate-day regimen, for 2 to 3 additional months). About 50% of patients so treated will experience a decrease in proteinuria to subnephrotic levels. Complete remissions occasionally occur. However, relapses of proteinuria are common when corticosteroids are tapered or discontinued. Such relapsing, partially corticosteroid responsive patients might benefit from the addition of cyclophosphamide, chlorambucil, or even cyclosporine or mycophenolate mofetil (MMF) to the regimen, although information on the therapeutic efficacy and safety of these agents in pure MesPGN is limited.

Collagen-Vascular (Rheumatic) Diseases Associated with Glomerular Lesions
SLE (see Chapter 25)
Rheumatoid arthritis
Mixed connective tissue disease
Rheumatic fever
Ankylosing spondylitis
Reiter's syndrome
Dermatomyositis/polymyositis
Scleroderma
Relapsing polychondritis
Systemic or renal limited polyangiitis (see Chapter 24)

Figure 27.3 Collagen-vascular (rheumatic) diseases associated with glomerular lesions. SLE, systemic lupus erythematosus.

Patients with persistent treatment-unresponsive nephrotic syndrome will almost invariably progress to ESRD during a period of several years. Whereas transplantation is not contraindicated, those patients who do progress to ESRD rapidly and who develop superimposed FSGS may have a high risk of recurrence of proteinuria and FSGS in the transplanted kidney.

GLOMERULONEPHRITIS WITH RHEUMATIC DISEASE

Several so-called collagen-vascular diseases other than SLE may be complicated by GN (Fig. 27.3). This section covers the glomerulonephritides that accompany rheumatoid arthritis, mixed connective tissue disease,⁶ polymyositis and dermatomyositis, acute rheumatic fever, scleroderma, and relapsing polychondritis. IgA nephropathy may also be seen in association with the seronegative spondyloarthropathies.

Rheumatoid Arthritis

A wide variety of glomerular, tubulointerstitial, and vascular lesions of the kidney may complicate rheumatoid arthritis (Fig. 27.4). Clinical abnormalities, including abnormal urinalyses (hematuria, leukocyturia, proteinuria), and reduced renal function are common in patients with rheumatoid arthritis, particularly those with severe or long-standing disease. Membranous nephropathy (MN) (see Chapter 20) is the most common glomerular lesion encountered. This may be due to the underlying disease itself or its therapy (parenteral or oral gold or penicillamine). The presence of HLA-DR3 increases the risk for development of MN in a patient with rheumatoid arthritis.

The course of MN in association with rheumatoid arthritis, in the absence of drugs, is similar to that of the idiopathic disease, although spontaneous remissions appear less likely to occur. By comparison, MN associated with drugs used to treat rheumatoid arthritis is most likely to remit after discontinuance of the drug therapy.⁷ Such remissions may take many months to occur. Nevertheless, 60% to 80% of patients with drug-induced MN in a setting of rheumatoid arthritis will remit within a year of stopping treatment.

Secondary (AA) amyloidosis is found in 5% to 20% of patients with rheumatoid arthritis undergoing renal biopsy. Nephrotic

Renal Disease in Rheumatoid Arthritis
Glomerular Lesions that May Be Direct Complications of the Disease
MN
MesPGN (\pm IgA or IgM deposits)
Diffuse proliferative GN
Necrotizing and crescentic GN (rheumatoid vasculitis)
Amyloidosis (AA type)
Glomerular Lesions Associated with Agents Used in the Treatment of Rheumatoid Arthritis
Gold: MN, MCD acute tubular necrosis
Penicillamine: MN, crescentic GN, MCD
NSAIDs: acute tubulointerstitial nephritis (TIN) with MCD, acute tubular necrosis, MCD without TIN
Cyclosporine: chronic vasculopathy and TIN, focal and segmental glomerulosclerosis (?)
Azathioprine/6-mercaptopurine: acute interstitial nephritis
Pamidronate: focal segmental glomerulosclerosis

Figure 27.4 Renal disease in rheumatoid arthritis. MCD, minimal change disease; MesPGN, mesangial proliferative glomerulonephritis; MN, membranous nephropathy; NSAIDs, nonsteroidal antiinflammatory agents; TIN, tubulointerstitial nephropathy.

syndrome and progressive renal failure are common. AA amyloidosis is discussed in detail in Chapter 26.

The use of nonsteroidal anti-inflammatory drugs (NSAIDs) may also produce tubulointerstitial nephritis or MCD (see also Chapters 60 and 17).⁸ A severe, necrotizing polyangiitis may sometimes complicate the course of long-standing rheumatoid arthritis (rheumatoid vasculitis).⁸ The patients may have profound reduction in C3 levels, striking elevation of rheumatoid factors, and marked polyclonal hypergammaglobulinemia. Renal involvement in rheumatoid vasculitis is relatively uncommon for poorly understood reasons.

Mixed Connective Tissue Disease

Mixed connective tissue disease is characterized by features that overlap with those of SLE, scleroderma, and polymyositis. Typically, the serum of such patients contains high-titer autoantibodies to extractable nuclear antigens (ribonucleoprotein-extractable nuclear antigen, U1 ribonucleoprotein antigen). Low titers of anti-double-stranded DNA antibody may also be found. Renal disease, originally thought to be quite rare, is found in 10% to 50% of patients, most frequently MN and MesPGN.⁹ Treatment with corticosteroids is generally effective, but some patients exhibit progressive CKD. Patients with severe GN may respond to treatment regimens similar to those used in the treatment of lupus nephritis (see Chapter 25).

Polymyositis and Dermatomyositis

These related collagen-vascular diseases are characterized by inflammatory lesions in muscle and variable skin lesions and often include Raynaud's phenomenon.¹⁰ On occasion, patients

develop proteinuria and hematuria secondary to MesPGN with IgM deposits. Acute kidney injury (AKI) may rarely supervene when severe muscle injury and myoglobinuria are present. Treatment with corticosteroids may, at least in part, ameliorate the renal manifestations in concert with improvement in the muscle and skin manifestations.

Acute Rheumatic Fever

Acute rheumatic fever secondary to a pharyngeal infection with a rheumatogenic strain of group A β -hemolytic streptococci is seldom accompanied by renal disease (see Chapter 55).¹¹ Post-streptococcal GN and acute rheumatic fever almost never coexist because of the distinct difference between nephritogenic and rheumatogenic strains of streptococci. In addition, cutaneous streptococcal infections are never associated with acute rheumatic fever sequelae. Nevertheless, on rare occasions, MesPGN has been associated with acute rheumatic fever.¹¹ It usually is manifested with hematuria with scant proteinuria and often resolves with appropriate treatment and control of acute rheumatic fever.

Ankylosing Spondylitis and Reiter's Syndrome (Seronegative Spondyloarthropathies)

The seronegative spondyloarthropathies and oligoarticular arthropathies may from time to time be associated with mesangial IgA deposition and MesPGN. Clinical manifestations are usually mild and nonprogressive. AA amyloidosis may complicate long-standing ankylosing spondylitis.

Scleroderma (Systemic Sclerosis)

Scleroderma is a heterogeneous disorder of unknown etiology and pathogenesis characterized by uncontrolled expansion of connective tissue in the skin and other visceral organs. There is also a marked tendency to produce vascular thickening and narrowing. Clinical manifestations vary from increased connective tissue in localized patches of skin (morphea) to diffuse and generalized disease (systemic sclerosis). The latter pattern leads to thickening of the skin of the face and hands, telangiectasia, Raynaud's phenomenon, tendon friction rubs, and sclerodactyly. A characteristic pattern of blood vessel abnormalities is seen in the nail beds. Visceral involvement in the systemic form causes interstitial pulmonary fibrosis, loss of esophageal and other gastrointestinal motility, restrictive cardiomyopathy, and renal disease. Limited forms of the disease (CREST syndrome: calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) also occur but are seldom associated with renal disease. The disorder is seen more frequently in females, with an onset usually in young adults. Approximately 90% of patients will have a speckled pattern of fluorescent ANA; 20% will have detectable antibody to topoisomerase I (Scl-70). Anticentromere antibody is strongly associated with the CREST syndrome. Anti-DNA polymerase is associated with a poor prognosis and a high prevalence of renal involvement. Rarely, the visceral abnormalities may occur in the absence of cutaneous lesions (scleroderma sine scleroderma).

Renal involvement in scleroderma can be quite varied, from a low-grade proteinuria and slight impairment of glomerular filtration rate (GFR), to a more marked reduction in renal blood flow leading to a greatly elevated filtration fraction due to a mild MesPGN, to severe AKI. The last is referred to as scleroderma

Figure 27.5 Scleroderma. **A**, Two interlobular arteries, one transversely and one tangentially cut, show a pronounced subendothelial thickening with weakly periodic acid–Schiff–positive mucinous material and myofibroblasts (arrow). **B**, Fragmented erythrocytes (schistocytes) can be seen in the Goldner elastica stain in red (arrow). The process is limited to the intima as the lamina elastica interna is preserved. Surrounding tubules are collapsed and have atrophic epithelia due to postarteriolar ischemia. (Courtesy H. J. Groene, Heidelberg, Germany.)

renal crisis and consists of severe (hyperreninemic) hypertension, encephalopathy, systolic and diastolic congestive heart failure, and AKI. There is often an accompanying microangiopathic hemolytic anemia with schistocytes in the peripheral blood film and greatly elevated serum lactate dehydrogenase levels. On occasion, AKI may develop in the absence of hypertension. AKI results from primary involvement of the arcuate and interlobular arteries (Fig. 27.5) and may be superimposed on lesions of hypertensive emergencies (malignant hypertension, such as fibrinoid necrosis of the afferent arterioles) and ischemic glomerular changes, such as wrinkling of the capillary wall and thickening of the basal lamina. The prognosis of scleroderma crisis has remarkably improved with the use of angiotensin-converting enzyme (ACE) inhibitors. In one study, ACE inhibitor treatment was associated with better patient survival at 1 year (75% versus 15%) and with significant preservation or recovery of renal function.¹² Transplantation may be a reasonable treatment option, but progression of disease in other visceral organs may limit life expectancy.

Relapsing Polychondritis

Polychondritis is a chronic relapsing disorder characterized by destructive inflammation of cartilage (ear, nose, trachea, costal cartilage) and may be associated with crescentic GN, MesPGN, or MN. Lesions of cartilage may lead to deformities (saddle nose, floppy ears, tracheal collapse or stenosis), and the renal disease may be severe and progressive, leading to renal failure. Aggressive management of progressive disease with corticosteroids and cytotoxic agents (cyclophosphamide) is indicated to control both the systemic and renal manifestations.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome (aPLA syndrome) is a prothrombotic disorder characterized by venous and arterial thrombosis and by the presence of circulating autoantibodies to phospholipid-protein complexes, including those of the coagulation cascade.^{13,14} The syndrome was first recognized by Hughes in 1983 and in the succeeding quarter-century has been described to have protean manifestations ranging from migraine headaches to multiple thrombosis and multiorgan failure (“catastrophic” aPLA syndrome). The clinical features are quite varied, and a high degree of clinical suspicion is required for early diagnosis. Neurologic symptoms and signs are common, including transient cerebral ischemic attacks (TIA), strokes, migraine, seizures, myelitis, and balance and sensory disturbances (often resembling multiple sclerosis). Cardiovascular problems, such as pulmonary hypertension, premature atheromatous disease, renal artery stenosis, and myocardial infarction, are common. Livedo reticularis is an important diagnostic clue (Fig. 27.6). Adrenal infarction or hepatic venous thrombosis may lead to acute adrenal insufficiency or Budd-Chiari syndrome, respectively. Visual loss, field defects, anosmia, aseptic bone necrosis, fracture, spinal claudication, and autonomic dystrophy are other less well described complications. Repeated pregnancy loss (two or more) is observed often. The kidneys are frequently involved with a form of thrombotic microangiopathy (see Chapter 28).

The aPLA syndrome may occur as a “primary” form without any known systemic disease or may accompany SLE (see also Chapter 25). The aPLA syndrome (primary or SLE related) should always be suspected whenever a history of migraine, headache, TIA or stroke, multiple pregnancy loss, or arterial or venous thrombosis or a family history of autoimmune disease is elicited.

Figure 27.6 Livedo racemosa in a patient with antiphospholipid syndrome. Note reticulated skin changes (arrows) in addition to psoriasis lesions. (Courtesy J. Floege, Aachen, Germany.)

Laboratory testing will commonly reveal an autoantibody to phospholipids (anticardiolipin, anti- β_2 -glycoprotein 1, or prothrombin), but “antibody-negative” aPLA syndrome has been described.¹³⁻¹⁵ False-positive test results for syphilis and a “lupus anticoagulant” are frequent. A prolonged prothrombin or partial thromboplastin time that does not correct when plasma is diluted 1:1 with normal plasma is found in such circumstances. Antiphospholipid antibodies may also cross-react with platelet factor 4-heparin complex and thus may be associated with a “false positive” for antibody in heparin-induced thrombocytopenia,¹⁶ giving rise to significant clinical confusion. Mild thrombocytopenia is common (platelet counts around 100,000/mm³, but usually not less than 80,000/mm³). This may be an *in vitro* phenomenon related to the effect of the aPLA antibody on platelet membrane biology. A mild hemolytic anemia (Coombs negative or positive) may coexist, giving rise to confusion with thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, and Evans syndrome. A frank microangiopathic hemolytic anemia is relatively uncommon.

In the primary aPLA syndrome, overt renal manifestations are generally mild (proteinuria, hematuria, hypertension, reduced renal function) and are frequently absent. Nephrotic syndrome is relatively rare. In aPLA syndrome associated with SLE, the renal manifestations are determined largely by the severity of the underlying glomerular lesions, but the coexistence of the aPLA syndrome adds a dimension of vascular disease (microangiopathy) that contributes to a worsened prognosis and to a multiplicity of extrarenal manifestations (neurologic, cardiovascular, osseous, ophthalmologic, hepatic, visceral, and obstetric) (see also Chapter 25).

The therapy for aPLA syndrome is difficult. Immunosuppressive agents, such as corticosteroids or cytotoxic agents, even when they are used to control SLE, have yielded disappointing results. Symptomatic patients are best treated with anticoagulation. Aspirin (or clopidogrel) can be used routinely in mild cases. Combinations of aspirin and low-dose warfarin might be effective, but the risk of bleeding may be increased. Warfarin is the mainstay of treatment in severe cases, with the international normalized ratio (INR) adjusted to a level depending on symptoms; INR between 2.0 and 3.5 may be required. Low-molecular-weight heparin (subcutaneous or intravenous) is the treatment of choice for pregnancy complicated by aPLA syndrome and is also useful in alleviating migraine headache. High-dose intravenous IgG can have dramatic beneficial effects, especially in acutely evolving disease associated with SLE. The benefits of newer immunomodulating agents, such as rituximab and MMF, have not been adequately evaluated in aPLA syndrome. Intensive plasma exchange (plus immunosuppression) may rarely be effective in pregnancy¹⁷ but has not been fully evaluated in other circumstances, such as in aPLA syndrome associated with SLE.

GLOMERULONEPHRITIS ASSOCIATED WITH MALIGNANT DISEASE

Many malignant disorders and their treatment may be complicated by the development of glomerular lesions.¹⁸ Furthermore, the treatment of glomerular disease with certain agents may give rise to neoplasia. Malignant neoplasms may also be associated with a wide variety of fluid, electrolyte, acid-base, divalent ion, tubulointerstitial, and vascular disorders, including direct invasion of the renal parenchyma by neoplastic cells.

Major Glomerular Lesions Associated with Neoplastic Disease	
Glomerular Disease	Commonly Associated Malignancy
MN	Colon, breast, stomach, and lung cancer
MCD	Hodgkin's lymphoma, pancreatic cancer, mesothelioma, prostate cancer
FSGS	Leukemia, lymphoma
MPGN	Chronic lymphocytic leukemia, lymphoma (some associated with HCV)
IgA nephropathy	Lung carcinoma
Crescentic GN/systemic vasculitis	Lung carcinoma
Systemic amyloidosis AL type	Multiple myeloma, Waldenström's macroglobulinemia
Systemic amyloidosis AA type	Carcinoma (especially renal)
Cryoglobulinemic GN	Chronic lymphocytic leukemia (often hepatitis C associated)
Light-chain nephropathy	Lymphoma, myeloma
Fibrillary (immunotactoid) GN	Lymphoma
Hemolytic-uremic syndrome	Gastric cancer, mucin-producing cancer

Figure 27.7 Major glomerular lesions associated with neoplastic disease. FSGS, focal segmental glomerulosclerosis; HCV, hepatitis C virus; MCD, minimal change disease; MN, membranous nephropathy; MPGN, membranoproliferative glomerulonephritis.

The glomerular lesions commonly observed in association with neoplastic processes are listed in Figure 27.7. MN is the most common lesion (see also Chapter 20). Approximately 7% to 20% of patients with MN will be found to have an underlying malignant neoplasm. Most patients are adults older than 50 years; however, despite the increasing frequency of malignant disease with age in the general population, epidemiologic studies support the notion that the prevalence of malignant disease is higher in patients with MN than in age-matched controls.¹⁹ In addition, remissions (albeit temporary) can be achieved by surgical removal or chemotherapy of the neoplastic disease, and relapses may develop with recurrence of tumor. Furthermore, tumor neoantigens or antibodies have been detected within the glomerular deposits, suggesting an immune complex pathogenesis. In about one third of patients, the neoplastic disorder is already evident before the development of glomerular lesions; in about one third, it is discovered concomitantly with the onset of glomerular disease; and in about one third, the neoplastic process is detected after the diagnosis of glomerular disease. MN occurring with an underlying malignant neoplasm can closely resemble the idiopathic disease both clinically and morphologically, so it is prudent to undertake an exploration for possible malignant disease in any patient older than 50 years who presents with an apparent “idiopathic” MN. This can consist of a careful physical examination, several stool specimens for occult blood, colonoscopy, computed tomographic (CT) scan of the chest (especially in smokers), mammography (in women), and prostate-specific antigen determination (in men). Some studies have also suggested that prominent

IgG1 and IgG2 instead of IgG4 deposits in the glomeruli are suggestive of a malignant cause or underlying lupus nephritis. The role of searching for specific autoantibodies in MN remains relatively unexplored territory.

Less frequent lesions observed in patients with neoplasia include minimal change, FSGS, proliferative GN (including crescentic GN), thrombotic microangiopathy, monoclonal immunoglobulin deposition diseases (MIDD), and amyloidosis. MCD may be associated with lymphoma (particularly Hodgkin's disease) and certain other cancers (pancreas, mesothelioma, prostate). Membranoproliferative GN (MPGN) may be associated with chronic lymphocytic leukemia and lymphoma. FSGS may also occasionally be encountered in patients with underlying malignant disease, including leukemia and lymphoma. IgA nephropathy and crescentic GN may be associated with lung cancer. Vasculitis accompanied by crescentic GN, often resembling Henoch-Schönlein purpura, has been reported with several malignant neoplasms, most notably lung cancer.

Systemic amyloidosis (AL type) may affect the kidney and produce nephrotic syndrome and renal failure in 10% to 15% of patients with multiple myeloma and rarely in association with Waldenström's macroglobulinemia (see Chapter 26). Carcinomas, including renal cell carcinoma, are also rarely complicated by amyloidosis, which is usually of the AA variety. MIDD (see Chapter 26) may accompany lymphomas and leukemias. Light-chain nephropathy, in which deposits of either κ or γ light chain are found in the glomerular capillaries and tubular basement membranes, may occur in association with a variety of neoplastic lymphoproliferative states (see also Chapter 26).

Thrombotic microangiopathy, producing renal cortical necrosis or glomerular lesions resembling MPGN, may be seen in association with disseminated cancer (carcinoma of the stomach) and other mucin-producing carcinomas. It may also appear secondary to treatment with certain antineoplastic agents, especially mitomycin (mitomycin C; see also Chapter 28).

Interferon treatment, used in the management of certain malignant neoplasms, may rarely cause MCD, often in association with interstitial nephritis; rarely it may also cause focal segmental glomerulosclerosis (FSGS) (see Chapter 18).

OTHER UNCOMMON DISORDERS

Lipoprotein Glomerulopathy

Lipoprotein glomerulopathy is believed to be caused by an abnormality in lipoprotein metabolism²⁰ and is characterized by extensive deposits of apolipoproteins A, B, and E in the glomeruli (mostly apolipoprotein E), leading to greatly expanded capillaries filled with a pale-staining, mesh-like substance having the appearance of lipid “thrombi” (Fig. 27.8). Clinically, there may be heavy proteinuria with nephrotic syndrome. Apolipoprotein B and E levels are increased in plasma in association with a type III hyperlipoproteinemia. The apolipoprotein E usually shows a heterozygous E2/E3 or E2/E4 phenotype, but homozygosity for apolipoprotein E2 or E3 has also been observed. Homozygous apolipoprotein E2 is also seen in familial type III hyperlipoproteinemia. Low low-density lipoprotein receptor binding and high heparin affinity may explain some of the pathogenetic processes in lipoprotein glomerulopathy. The disease can be associated with psoriasis²¹; otherwise, there are no distinctive clinical features. Familial cases have strongly suggested a hereditary abnormality. The disorder may recur in the renal transplant. Treatment with bezafibrate or fenofibrate may be effective.^{22,23}

(Trichrome stain; magnification $\times 260$.) **B**, The granules stain positively with oil red O and antilipoprotein E antisera. (Oil red O; magnification $\times 260$.) (Modified from reference 1.)

Lecithin–Cholesterol Acyltransferase Deficiency

Lecithin–cholesterol acyltransferase (LCAT) deficiency is an autosomal recessive disorder.²⁴ The mutations are on the *LCAT* gene located on chromosome 16q22.²⁵ The clinical characteristics include corneal opacities (misty deposits, also known as “fish eye”), normocytic normochromic anemia, premature atherosclerosis, low high-density lipoprotein and α -lipoprotein levels, and elevated low-density lipoproteins. Proteinuria (including the nephrotic syndrome), hypertension, and progressive renal failure are the main renal manifestations. On light microscopy, the glomeruli reveal foam cells, intimal hyperplasia, and thickening of the basement membrane with effacement of the foot processes (Fig. 27.9). Progressive renal failure is the rule; however, it is of slow and insidious onset and is usually first detected by the fourth decade of life. Treatment is generally ineffective, but theoretically, an inhibitor of hepatic acyl coenzyme A–cholesterol acyltransferase activity might be of benefit.²⁵

Collagen III Glomerulopathy

Collagen III glomerulopathy (also known as collagenofibrotic glomerulopathy) is an autosomal recessive systemic disorder with prominent renal manifestations that may be a *forme fruste* of nail-patella syndrome (see Chapter 46) because the glomerular abnormalities are similar.^{26,27} Nevertheless, patients with collagen III glomerulopathy lack the typical skeletal abnormalities observed in the nail-patella syndrome. Clinically, patients present

Figure 27.9 Lecithin–cholesterol acyltransferase deficiency. Note the irregular thickened glomerular capillary walls containing clear vacuoles, which are characteristic of the lesion. (Periodic acid–Schiff; magnification $\times 1000$.) (Modified from reference 1.)

with proteinuria and slowly progressive renal failure. Patients may be of any age, and males predominate. On light microscopy, the glomeruli are enlarged with a marked expansion of the mesangial matrix by material weakly positive for staining with periodic acid–Schiff (Fig. 27.10). Conventional immunofluorescence microscopy is negative, but antisera to collagen type III will strongly react with the glomerular deposits. Electron microscopy shows bundles spirally arranged and frayed fibrillar deposits (Congo red negative) with periodicity characteristic of collagen. Similar deposits may be found in the spleen, liver, myocardium, and thyroid in fatal cases. No treatment is effective, and there are no data yet on recurrent disease after renal transplantation, but because of the systemic nature of the disease, such recurrences would be likely.

Fibronectin Glomerulopathy

Fibronectin glomerulopathy is a rare, autosomal dominant, non-amyloid, fibrillary glomerular disease with onset usually in early adolescence with proteinuria, microhematuria, hypertension, distal (type 4) renal tubular acidosis, and slowly progressive renal failure.^{28,29} The gene responsible for the disorder maps to chromosome 1q32 near markers D1S2872 and D1S2891.³⁰ Most patients reach ESRD between the second and sixth decades of life. The renal pathology usually reveals enlarged, hyperlobular, and normocellular glomeruli with a homogeneous or fibrillar material (on periodic acid–Schiff staining) in the mesangium and subendothelium (Congo red negative). Electron microscopy shows randomly oriented fibrils (12 to 16 nm wide and 120 to 170 nm long). Immunofluorescence is negative for antibody and complement components but will stain brightly with use of an antifibronectin antibody. The pathogenesis of the disease is unknown, although mice “knocked out” for uteroglobin develop a similar lesion. However, studies in humans have not documented any linkage to genes for uteroglobin or fibronectin. The differential diagnosis includes other disorders associated with fibril deposition (see Chapter 26). There is no known effective treatment.

Nephropathic Cystinosis

Late-onset adult cystinosis is a variant of typical pediatric cystinosis in which the mutations in the *CTNS* gene result in a milder

Figure 27.10 Electron microscopy of collagen III glomerulopathy (collagenofibrotic glomerulopathy). **A**, Fine fibrils occur in the mesangial and subendothelial areas. (Magnification $\times 3000$). **B**, These fibrils are randomly oriented with typical periodicity and average 30 nm in diameter. The fibrils are strongly positive for staining with periodic acid–Schiff stain and react with anticollagen III antibodies. (Magnification $\times 15,000$.) (Modified from reference 1.)

phenotype. These patients may present with glomerular disease during the teenage years. Nephrotic syndrome may occur, and the glomerular lesions resemble FSGS except that crystals of cystine are found in glomerular and tubular epithelial cells.^{3,31} Patients with cystinosis may also have blond hair, photophobia, hypothyroidism, corneal deposits, rickets, and Fanconi syndrome (see also Chapter 48).

Miscellaneous Storage Diseases and Other Unusual Glomerular Lesions

A variety of diseases associated with storage of abdominal lipids or carbohydrates in tissue may provoke glomerular lesions; these include Hurler's syndrome (type I mucopolysaccharidoses), von Gierke's disease (glycogen storage disease), Gaucher's disease, Refsum's disease, nephrosialidosis, and I-cell disease (mucopolysaccharidosis type II). Juvenile malabsorption of vitamin B₁₂ with megaloblastic anemia (Imerslund syndrome) can be associated with prolonged glomerular proteinuria, but progressive renal disease does not develop. Asphyxiating thoracic dystrophy (Jeune's syndrome) is associated with glomerular, tubular, and interstitial abnormalities. Hereditary osteolysis causing arthralgias and deformities of wrists and ankles can be accompanied by chronic GN. The nail-patella syndrome and Fabry's disease are discussed in Chapter 46.

"Idiopathic" Nodular Glomerulosclerosis

An intercapillary nodular expansion of the mesangium encroaching on the glomerular capillary lumina is characteristically called the Kimmelstiel-Wilson lesion and is most commonly associated with diabetes mellitus and proliferative diabetic retinopathy (see Chapter 29). However, in recent years, a small group of patients have been described in whom a similar or identical lesion is seen in the absence of any overt features of diabetes mellitus or disordered glucose metabolism or other known causes of a similar lesion (such as κ light-chain nephropathy [see Chapter 26], chronic thrombotic microangiopathy, monoclonal immunoglobulin deposition diseases, fibrillary GN, and fibronectin glomerulopathy). Thus, idiopathic nodular glomerulosclerosis is a diagnosis of exclusion. The first examples of this new disorder were recognized in 1989,³² and approximately 50 additional cases have subsequently been reported.^{33–35} Whereas some of these patients may have had intermittent manifestation of diabetes or only mild abnormalities of glucose homeostasis, such as an abnormal glucose tolerance test result, most have not had any features conventionally used to define the presence of diabetes mellitus (i.e., normal fasting blood glucose concentration and hemoglobin A_{1c} measurements). Thus, the intercapillary nodular lesion does not appear to require prolonged abnormal glucose homeostasis for its generation.

The clinical features are nonspecific and nondiagnostic. Patients with idiopathic nodular glomerulosclerosis are usually older (average age of about 70 years), and nephrotic syndrome is a common presentation. A heavy smoking history and longstanding hypertension are frequently present, but the role of these abnormalities in the pathogenesis of the lesion is unknown.

The pathology includes typical intercapillary nodular glomerulosclerosis with thickening of the GBM and varying degrees of arteriolonephrosclerosis and hyalinosis identical to the diabetes-associated Kimmelstiel-Wilson lesions. No electron-dense or organized deposits are seen on electron microscopy. The GBM and tubular basement membrane may "stain" with IgG and albumin on immunofluorescence. Neovascularization can be seen within the nodules.

The prognosis is poor and relates to the persistence of nephrotic-range proteinuria. Most patients will progress to ESRD, sometimes quite rapidly. The 50% renal survival point in those who continue to smoke heavily is about 1 year after diagnosis. There is no known effective therapy, other than angiotensin inhibition to reduce the proteinuria. Stopping smoking may be beneficial and should be urged for all patients with this diagnosis.

Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

Piero Ruggerenti, Paolo Cravedi, Giuseppe Remuzzi

DEFINITIONS

Thrombotic microangiopathy (TMA) is characterized by an acute syndrome of microangiopathic hemolytic anemia, thrombocytopenia, and variable signs of organ injury due to platelet thrombosis in the microcirculation.¹ Depending on the predominant distribution of the lesions—kidney or central nervous system (CNS)—two pathologically identical but clinically distinct entities are described: hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). HUS usually affects young children and is characterized by acute kidney injury (AKI) and absent or minimal neurologic abnormalities. TTP occurs in adults and is characterized by severe neurologic involvement in most cases and variable renal involvement. In some patients, features of HUS and TTP may coexist. Injury to the endothelial cell is the central and likely inciting factor in the sequence of events leading to TMA. Loss of physiologic thromboresistance, leukocyte adhesion to damaged endothelium, complement consumption, abnormal von Willebrand factor (vWF) release and fragmentation, and increased vascular shear stress may then sustain and amplify the microangiopathic process. Toxins, autoantibodies, pregnancy, systemic diseases, and drugs have been associated with TMA (Fig. 28.1). In most of these cases, early recognition and treatment of the underlying condition are therefore of paramount importance for remission to be achieved.¹

CLINICAL AND LABORATORY SIGNS

TMA is characterized by thrombocytopenia (often with purpura but rarely with severe bleeding), microangiopathic hemolytic anemia, AKI that may be associated with anuria, neurologic deficits, and fever. Thrombocytopenia and hemolytic anemia are the key laboratory abnormalities. Thrombocytopenia is caused by platelet aggregation in the microcirculation; hemolytic anemia is due to mechanical fragmentation of erythrocytes during their passage through the narrowed vessels. Thrombocytopenia is usually more severe in TTP than in HUS. At the onset of TTP, platelet counts may be less than 20×10^9 cells/l. In HUS, values between 30×10^9 and 100×10^9 cells/l are frequent; however, values can be normal. Anemia is usually severe, with hemoglobin concentrations below 6.5 mg/dl in about 40% of cases. Hyperbilirubinemia (mainly indirect), reticulocytosis, circulating free hemoglobin, and low haptoglobin levels are typical. The serum lactate dehydrogenase (LDH) level is extremely high, reflecting hemolysis but also, in some patients, diffuse tissue infarction. Platelet count and serum LDH level are useful parameters for both diagnosis and response to treatment. Fragmented red blood

cells (schistocytes) with the typical appearance of a helmet in the peripheral smear (Fig. 28.2) and a negative Coombs test result (with the exception of neuraminidase-associated TMA) are needed to confirm the microangiopathic nature of hemolysis. There is often leukocytosis with a left shift in Shiga toxin (Stx)–associated HUS, whereas leukocytes are usually normal in atypical HUS (aHUS) and TTP. Hypocomplementemia (low serum C3 levels) is occasionally present. Prothrombin time and partial thromboplastin time, factor V, factor VIII, and fibrinogen are normal in most cases. Determination of total hemolytic activity (CH50) usually does not help the diagnosis. AKI is usually associated with mild proteinuria (usually 1 to 2 g/day) and few red blood cells and casts in the urinary sediment. Seizure and coma may occur in TTP and, much less frequently, in HUS, often in the setting of severe or refractory hypertension.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of TMA is based on the preceding clinical and laboratory findings. Renal biopsy is indicated when the diagnosis is uncertain and thrombocytopenia is not severe. In case of thrombocytopenia, microangiopathic hemolytic anemia, and AKI, the differential diagnosis includes systemic vasculitis, hypertensive emergency, disseminated intravascular coagulation (DIC), and endemic Hantavirus infection. Other conditions that can cause an HUS-like picture include scleroderma and radiation injury. Vasculitis is usually characterized by other systemic symptoms, such as cutaneous rash (palpable purpura) and arthralgias; the platelet count is usually normal, and neurologic involvement is predominantly peripheral rather than central. Patients with hypertensive emergencies have a history of high blood pressure, very high systolic/diastolic blood pressure at the time of evaluation, and typical retinal lesions. DIC is usually associated with sepsis, shock, and obstetric complications; patients typically have consumption of all the components of the coagulation cascade, including fibrinogen, factor V, and factor VIII, with subsequent prolongation of prothrombin time and partial thromboplastin time. Hantavirus infection causes high fever, lumbar pain, AKI, and thrombocytopenia but usually no hemolysis.

PATHOLOGY

The diagnostic histologic lesions of TMA consist of widening of the subendothelial space and microvascular thrombosis. Electron microscopy best identifies the characteristic lesions of swelling and detachment of the endothelial cells from the basement membrane and the accumulation of fluffy material in the subendothelium (Fig. 28.3), intraluminal platelet thrombi, and partial or

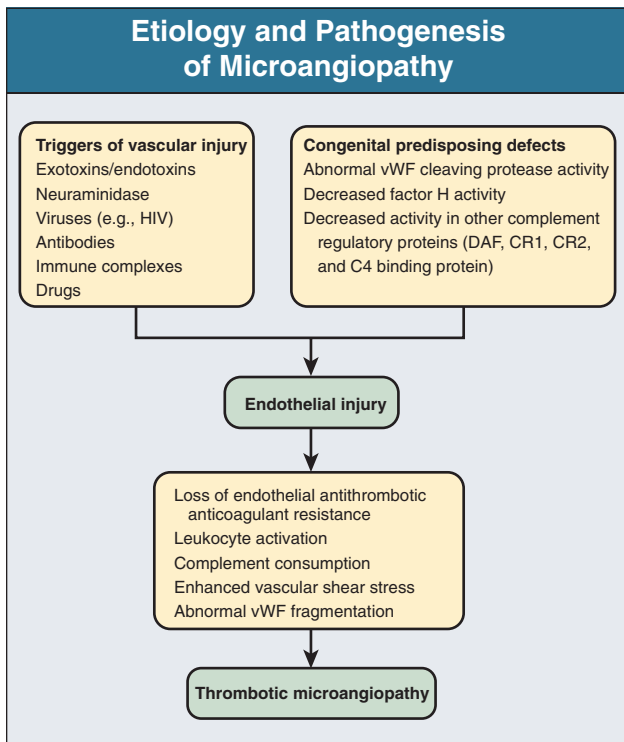

Figure 28.1 A suggested sequence of events leading to thrombotic microangiopathy (TMA) in predisposed subjects exposed to triggers of endothelial injury. HIV, human immunodeficiency virus; vWF, von Willebrand factor.

Figure 28.2 Peripheral blood smear from a patient with hemolytic-uremic syndrome (HUS). The presence of fragmented red blood cells with the appearance of a helmet (arrows) is pathognomonic for microangiopathic hemolysis in patients with no evidence of heart valvular disease.

complete obstruction of vessel lumina (Fig. 28.4). These lesions are similar to those seen in other renal diseases, such as scleroderma, malignant nephrosclerosis, chronic transplant rejection, and calcineurin inhibitor (CNI) nephrotoxicity. In HUS, microthrombi are present primarily in the kidneys; in TTP, they mainly involve the brain, where thrombi may repeatedly form and resolve, producing intermittent neurologic deficits. In pediatric patients, particularly in those younger than 2 years, and in those with HUS secondary to gastrointestinal infection with Stx-producing strains of *Escherichia coli*, the glomerular injury is predominant (Figs. 28.5 and 28.6). Thrombi and infiltration by leukocytes are common in the early phases of the disease and

Figure 28.3 Electron micrograph of a glomerular capillary in hemolytic-uremic syndrome (HUS). The endothelium is detached from the glomerular basement membrane (GBM); the subendothelial space is widened and occupied by electron-lucent fluffy material and cell debris (arrow). Beneath the endothelium is a thin layer of newly formed GBM.

Figure 28.4 Electron micrograph of a renal arteriole in hemolytic-uremic syndrome (HUS). The vascular lumen is completely occluded by thrombi. There is marked intimal edema with consequent separation of myointimal cells.

usually resolve after 2 to 3 weeks. Patchy cortical necrosis may be present in severe cases; crescent formation is uncommon. In idiopathic and familial forms and in adults, the injury mostly involves arteries and arterioles (Fig. 28.7), with secondary glomerular ischemia and retraction of the glomerular tuft (Fig. 28.8). The prognosis is good in the patients with predominant glomerular involvement, but it is more severe in those with predominant preglomerular injury. Focal segmental glomerulosclerosis (FSGS) may be a long-term sequela of acute cases of HUS and is usually seen in children with long-lasting hypertension and progressive chronic renal function deterioration.

The typical pathologic change of TTP involves occlusion of capillaries and arterioles in many organs and tissues by thrombi.

Figure 28.5 Glomerulus with its vascular pole from a patient with Shiga toxin-associated hemolytic-uremic syndrome (Stx-associated HUS). Strong staining with fluorescein-labeled antifibrinogen antibody occurs in the glomerulus and in the arteriolar wall.

Figure 28.6 Glomerulus from a patient with Shiga toxin-associated hemolytic-uremic syndrome (Stx-associated HUS). A marked thickening of the glomerular capillary wall occurs with many double contours.

These thrombi consist of fibrin and platelets, and their distribution is widespread. They are most commonly detected in kidneys, pancreas, heart, adrenals, and brain. Compared with HUS, pathologic changes of TTP are more extensively distributed, probably reflecting the more systemic nature of the disease.

CLINICAL FEATURES, MECHANISMS, AND MANAGEMENT OF SPECIFIC FORMS OF THROMBOTIC MICROANGIOPATHY

Differentiation of the various forms of TMA is important to predict disease outcome and to establish the correct therapeutic approach based on different clinical presentations (Figs. 28.9 to 28.11).

Thrombotic Microangiopathy Associated with Infectious Diseases

Shiga Toxin–Associated Hemolytic-Uremic Syndrome

Stx-associated HUS is the most frequent form of TMA.¹ It is associated with infection by certain strains of *E. coli* (mostly O157:H7 serotype) or *Shigella dysenteriae* type 1 that produce a powerful exotoxin. The human disease is caused by two distinct *E. coli* exotoxins, Stx1 and Stx2, almost identical to the toxin

Figure 28.7 Interlobular artery in a case of hemolytic-uremic syndrome (HUS) with severe vascular involvement. **A**, The vascular lumen is almost completely occluded. Changes include myointimal proliferation and reduplication of the lamina elastica. **B**, Thrombotic material and erythrocytes can be seen in the lumen and within the vascular wall.

Figure 28.8 Glomerulus from a patient with atypical hemolytic-uremic syndrome (aHUS) with predominant vascular involvement. Severe ischemic changes have occurred. Note the shrinkage of the glomerular tuft and marked thickening and wrinkling of the capillary wall.

produced by *S. dysenteriae* type 1. It is also referred to as D⁺ HUS because AKI is preceded by diarrhea.

The overall incidence is estimated to be 2.1 cases per 100,000 persons per year, with a peak incidence in children younger than 5 years (6.1/100,000 per year), although no age group is exempt. *E. coli* O157:H7 infection is most frequent in the warm summer months. Illness follows infection with Stx-producing *E. coli* a few

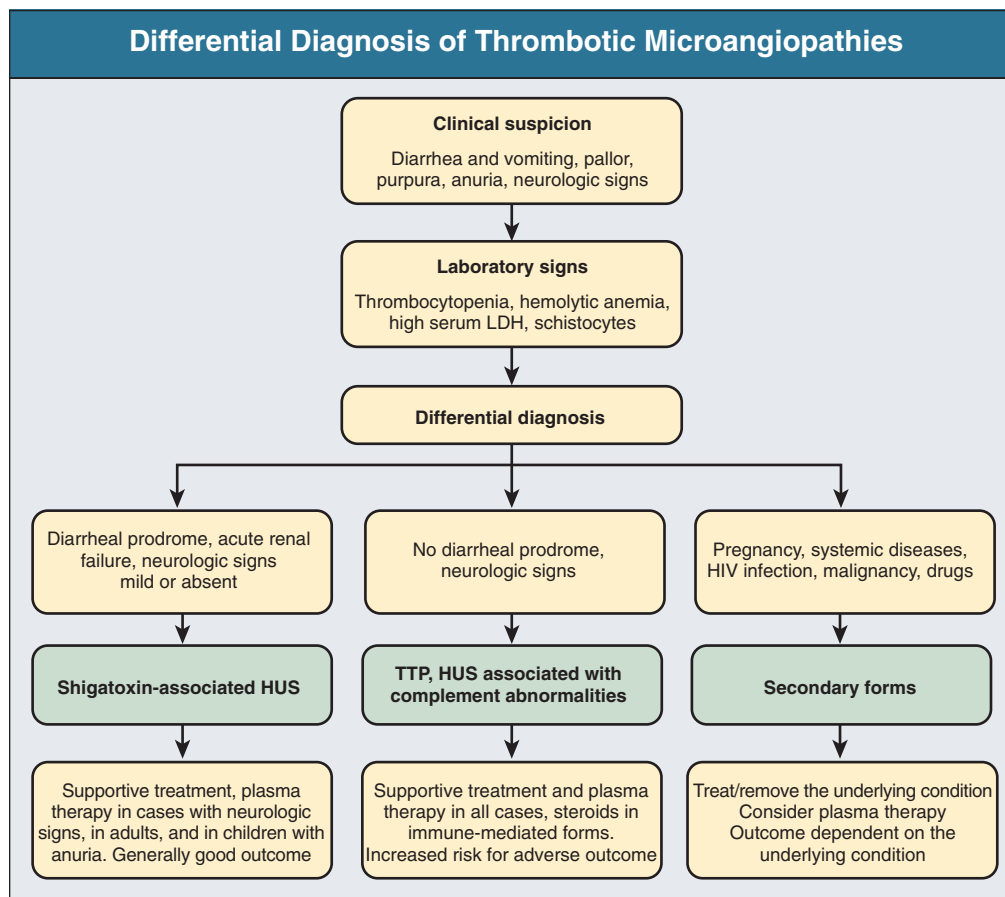

Figure 28.9 Algorithm for the differential diagnosis of thrombotic microangiopathies (TMAs). Patients with suggestive symptoms should be investigated for specific signs of microangiopathic hemolysis. In adults, secondary forms of the disease must be ruled out. Early diagnosis may help establish the most appropriate therapy. Specific therapies should be considered in children with anuria or neurologic signs, in cases without prodromal diarrhea, and in adult forms regardless of clinical presentation. In secondary forms, treatment or removal of the underlying disease is fundamental. HUS, hemolytic-uremic syndrome; LDH, lactate dehydrogenase; TTP, thrombotic thrombocytopenic purpura; HIV, human immunodeficiency virus.

Classification of Thrombotic Microangiopathies	
TMA associated with infectious disease	Shigatoxin-associated HUS Neuraminidase (pneumococcal)-associated TMA HIV infection
TTP associated with genetic or immune-mediated ADAMTS13 abnormalities	
HUS associated with genetic or immune-mediated abnormalities of the complement system	Genetically determined factor H deficiency Genetic membrane cofactor protein abnormalities Complement factor I deficiency Gain-of-function mutations of complement factor B Complement C3 mutations Immune-mediated factor H deficiency
Pregnancy-associated TMA	TTP HELLP syndrome Postpartum HUS
Systemic disease-associated TMA	Antiphospholipid, scleroderma, malignant hypertension Malignancy
Drug associated	
Transplant associated	De novo HUS Recurrent post-transplantation HUS

Figure 28.10 Classification of thrombotic microangiopathies (TMAs). HELLP, hemolysis, elevated liver enzymes and low platelet; HIV, human immunodeficiency virus; HUS, hemolytic-uremic syndrome; TMA, thrombotic microangiopathy; TTP, thrombotic thrombocytopenic purpura.

days later. HUS complicates enteric infection with *E. coli* O157:H7 in about 3% to 7% of sporadic cases and in 20% or more of the epidemic form. Mean onset of HUS is 6 days after the onset of diarrhea. Humans may be infected from contaminated milk and meat and fecally contaminated water or by contact with infected animals or human excretions.² Cattle represent the major natural reservoir of *E. coli* O157:H7. The most important route of Stx transmission is contaminated food (mainly undercooked ground beef including meat patties, roast beef, ham, turkey, cheese, potatoes, unpasteurized milk, and water). Secondary person-to-person contact is an important route of spread in institutional centers, particularly daycare centers and nursing homes. In these cases, the most important preventive measure is hand washing.

After oral ingestion of contaminated food or water, *E. coli* reaches the gut, closely binds to the gastrointestinal mucosa, and causes cell death. In non-Stx-producing *E. coli* strains, this normally results in nonbloody diarrhea. Strains producing a large amount of Stx may damage the mucosal vasculature, causing hemorrhagic colitis. Once the toxin reaches the systemic circulation, microvascular damage develops at target organs, giving rise to the clinical manifestations of HUS or, less frequently, TTP. Stx1 and Stx2 bind to different epitopes of the specific glycolipidic receptors (Gb3 molecules) and also differ in binding affinity and kinetics.²

High concentrations of Stx block protein synthesis and destroy endothelial cells. If endothelial cells are exposed to sublethal Stx doses, which exert a minimal influence on protein synthesis only, a nuclear factor- κ B-mediated proinflammatory

Specific Therapies Used in Thrombotic Microangiopathy, Doses, Modalities of Administration, and Effectiveness			
Therapy	Dosing	Modality of Administration	Efficacy
Antiplatelet agents			
Aspirin	325–1300 mg/day	Oral	Anecdotal reports In TTP forms
Dipyridamole	400–600 mg/day	Oral	“ ”
Dextran 70	500 mg twice/day	Intravenous injection	“ ”
Prostacyclin	4–20 ng/kg/mln	Continuous intravenous infusion	“ ”
Antithrombotic agents			
Heparin	5000 U	Pulse intravenous injection	Anecdotal reports In HUS
	750–1000 U/hour	Continuous intravenous infusion	
Streptokinase	250,000 U	Pulse intravenous injection	“ ”
	100,000 U/hour	Continuous intravenous infusion	
Antioxidant agents			
Vitamin E	1000 mg/m ² /day	Oral	Anecdotal reports In HUS
Immunosuppressive agents			
Prednisone / prednisolone	200 mg tapered to 60 mg/day Then 5-mg reduction per week	Intravenous or oral during active disease then continue with oral	Probably indicated in patients with TTP and anti-ADAMTS13 autoantibodies or in aHUS with anti-factor H autoantibodies and in forms associated with autoimmune diseases
Immunoglobulins	400 mg/kg/day	Intravenous infusion	
Vincristine	1.4 mg/m ² on day 1	Intravenous injection	
	1 mg every 4 days	Intravenous injection up to 4 doses	
Rituximab	375 mg/m ² /week for 4 weeks	Intravenous injection	
Fresh frozen plasma			
Exchange Infusion	1–2 plasma volumes/day 20–30 ml/kg on day 1 10–20 ml/kg/day thereafter	Intravenous infusion, up to remission Intravenous Infusion Intravenous infusion up to remission	First-line therapy First-line therapy if plasma exchange is not available
Cryosupernatant	See plasma infusion/exchange	See plasma infusion/exchange	Instead of whole plasma in case of plasma resistance or sensitization
Solvent detergent treated	See plasma infusion/exchange	See plasma infusion/exchange	Instead of whole plasma to limit the risk of infections
Others			
Liver transplant			To cure complement genetic defect (factor H)
Ecuzumab	600 mg weekly for the first 4 weeks 900 mg every 14 days thereafter up to 6 months	Intravenous infusion	Reported efficacy in cases of aHUS due to factor H mutations and of aHUS recurrence after kidney transplant

Figure 28.11 Treatment options for thrombotic microangiopathies (TMAs). aHUS, atypical hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura. ADAMTS13, a disintegrin and metalloprotease with thrombospondin type 1 domain 13.

response is induced, favoring leukocyte-dependent inflammation.² Stx also induces loss of thromboresistance in endothelial cells. Thus, human microvascular endothelial cells pre-exposed to Stx1 at high shear stress induce early platelet activation and adhesion, followed by formation of organized thrombi dependent on endothelial P-selectin and platelet–endothelial cell adhesion molecule 1. Finally, higher than normal levels of plasminogen activator inhibitor type 1 indicate that fibrinolysis is substantially inhibited.²

Clinical findings typically include abdominal cramps and non-bloody diarrhea; diarrhea usually becomes bloody within a few days. Vomiting occurs in about 30% to 60% of cases and fever in 30%. Leukocytosis is usually present. Dialysis is required in 50% of cases and red blood cell transfusions in 75%; neurologic signs including stroke, seizure, and coma occur in 25%. Pancreatitis occurs in about 20% of cases. HUS is usually considered a

benign disease because about 90% of patients fully recover from the acute syndrome. However, 3% to 5% of patients die during the acute phase, and up to 5% have severe renal and extrarenal sequelae. Moreover, up to 40% of those recovering from the acute disease may develop during several years a form of progressive chronic kidney disease (CKD).

Age younger than 2 years, severe gastrointestinal prodromes, elevated white cell count, anuria early in the course of the disease, and cortical necrosis or involvement of more than 50% of glomeruli at renal biopsy are predictors of poor outcome. Anuria for more than 10 days or need for dialysis in the acute phase and proteinuria at 12-month follow-up are associated with an increased risk of chronic renal failure (CRF) in the long term. Diagnosis rests on detection of *E. coli* O157:H7 or, much less frequently, other *E. coli* serotypes in stool culture samples that may be present for several weeks even after symptoms. Analysis

of bacterial serotypes should be limited to patients with diarrhea, however. Serologic tests for antibodies to Stx and O157 lipopolysaccharide can be performed in research laboratories, and tests are being developed for rapid detection of *E. coli* O157:H7 and Stx in stools. Utility of anti-Stx antibody monitoring has never been proved in clinical practice, however.

In general, children with cramping or bloody diarrhea exposed to an identified case of Stx-associated HUS should receive a rapid stool test. Early etiologic diagnosis and hospitalization of children with acute Stx-producing *E. coli* colitis may prevent spreading of the pathogen and secondary cases.

Treatment

SUPPORTIVE THERAPY In children, Stx-associated HUS usually resolves spontaneously. Early diagnosis and improved supportive management of renal failure, anemia, hypertension, and fluid-electrolyte imbalance have played a major role in the significant reduction of mortality rates during the past decades. In infants, early peritoneal dialysis (PD) prevents fluid overload and uremic symptoms and may remove procoagulant substances from the plasma. Blood transfusions are often needed for symptomatic anemia. Bowel rest is important for the enterohemorrhagic colitis but is not needed in less severe cases with nonbloody diarrhea. In patients with Stx-*E. coli* gastrointestinal infection, antibiotics should be avoided unless the patient presents with severe systemic bacteremia.² Although a recent meta-analysis of 26 reports failed to show a higher risk of HUS with antibiotic use,² there is no reason to prescribe antibiotics because they do not improve the outcome of colitis, and bacteremia is only exceptionally found in Stx-HUS sustained by *E. coli* O157:H7 infection. On the contrary, they are recommended in Stx-HUS precipitated by *S. dysenteriae* type 1, in which bacteremia is common and patients eventually progress to death if antibiotics are not started early enough. Antimotility agents are contraindicated because they may exacerbate HUS by decreasing fecal excretion of *E. coli* and its toxins. A new agent to prevent organ exposure to Stx, SYNSORB-Pk, composed of silicon particles linked to globotriaosylceramide, given orally, failed to improve outcome over placebo.² In those HUS patients who suffer chronic renal damage, treatment should follow the general recommendations that apply to all patients with CKD (see Chapter 76).

PLASMA THERAPY AND OTHER SPECIFIC TREATMENTS In children with Stx-associated HUS, the long-term renal outcome and patient survival are not appreciably improved by plasma therapy.^{3,4} Two prospective controlled trials found that plasma infusion may limit short-term renal lesions but does not affect long-term renal outcome and survival of patients.^{3,4} Corticosteroids are ineffective and should be avoided because they increase the risk of colonic perforation in patients with active colitis. Heparin and antithrombotic agents increase the risk of bleeding and should be avoided. In adults with Stx-associated HUS, uncontrolled studies suggest that plasma exchange (up to 16 procedures, with 2.0 to 2.4 liters of plasma exchanged with fresh frozen plasma [FFP]) significantly lowers mortality rate and the risk of end-stage renal disease (ESRD).^{5,6} Moreover, comparative analyses of two large series of patients treated or not with plasma suggest that plasma therapy may decrease overall mortality of Stx-*E. coli* O157:H7-associated HUS. Thus, even if no prospective, randomized trial has definitely established so far whether plasma infusion or exchange may offer some specific benefit compared with supportive treatment alone in adults with HUS, plasma

infusion or exchange should be considered in adult patients, in particular in those with severe renal insufficiency and CNS involvement. Hence, we suggest its use in adult patients, in whom renal and neurologic involvement is usually more severe and sequelae more frequent than in children.

BILATERAL NEPHRECTOMY Very rare cases characterized by severe changes in the renal microvasculature may be complicated by refractory hypertension, persistent thrombocytopenia, and major neurologic dysfunction that expose the patient to an imminent risk of death. In these life-threatening situations, after all other therapeutic approaches have failed, bilateral nephrectomy may induce complete clinical and hematologic remission within 2 weeks.⁷ It is possible that removal of the kidneys eliminates a major site of vWF fragmentation, thus limiting platelet activation and further spread of microvascular lesions.

KIDNEY TRANSPLANTATION Kidney transplantation is effective and safe for those children with Stx-HUS who progress to ESRD. The recurrence rates range from 0% to 10%, and graft survival at 10 years is even better than in pediatric transplant recipients with other primary renal disease.²

Neuraminidase-Associated Thrombotic Microangiopathy This is a rare but potentially fatal complication of pneumonia or, less frequently, meningitis caused by *Streptococcus pneumoniae*.¹ Neuraminidase is a protease produced by this bacterium that exposes a specific cryptic antigen, Thomsen-Friedenreich, present on platelets and endothelial cell surface, to preformed circulating IgM antibodies with subsequent platelet aggregation and endothelial injury. The clinical picture is usually severe, with respiratory distress, anuria, neurologic involvement, and coma. The outcome is strongly dependent on the effectiveness of antibiotic therapy. The role of plasma therapy is controversial. In theory, plasma should be contraindicated in the adult because it contains antibodies against the Thomsen-Friedenreich antigen that may accelerate polyagglutination and hemolysis.⁸ However, in some cases, plasma therapy, in combination with corticosteroids, induces recovery. Leukocyte-poor erythrocyte preparations should be used to reduce the risk of allosensitization that might prevent a future kidney transplant.

Thrombotic Thrombocytopenic Purpura Associated with Genetic or Immune-Mediated ADAMTS13 Abnormalities

Studies suggest that most patients with TTP have a specific pathogenetic defect characterized by the inability to cleave ultra-large vWF (ULvWF). Normally, ULvWF multimers are synthesized in endothelial cells and are rapidly degraded by a specific protease as soon as they are secreted into the circulation.⁹ ULvWF multimers accumulate in patients with TTP and can attach to activated platelets, promoting their aggregation. They are normally cleaved by a metalloprotease, ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 domain 13).¹⁰ Low ADAMTS13 activity can result from a constitutive deficiency or circulating acquired IgG autoantibodies to different antigenic regions of the ADAMTS13 molecule in patients with acute TTP.¹¹ The pathogenetic role of this autoantibody is supported by its disappearance from the circulation when remission is achieved by effective treatment, and this occurs in parallel with the normalization of plasma vWF-cleaving

protease activity. Autoantibodies against ADAMTS13 have also been observed in patients developing TTP during treatment with antiplatelet drugs such as ticlopidine and clopidogrel.¹¹

The differential diagnosis of TTP associated with genetic or immune-mediated ADAMTS13 abnormalities is important to predict disease outcome and to guide specific treatments. Disease related to genetic defects may affect relatives and tends to recur in the same individual. Immune-mediated disease does not cluster in families, may unmask an underlying autoimmune disease or follow the exposure to certain drugs, and may have a chronic, relentless course that parallels the production of the ADAMTS13 autoantibody. The rationale of treatment is also different (see later discussion). Monitoring of the severity of ADAMTS13 deficiency and the levels of the autoantibodies is also important to monitor the patient's response to treatment. Levels of ADAMTS13 activity below 10% to 15% are characteristic of an active disease. Levels between 20% and 50% may not be associated with TTP and can frequently be found in patients with liver disease or in uremic patients.

Treatment

Plasma Exchange or Infusion The most effective treatment of genetic defects in ADAMTS13 is exchange of plasma (plasma exchange) or plasma infusion, whereas corticosteroids or rituximab combined with plasma exchange might lead to long-lasting clearance of anti-ADAMTS13 antibodies in patients with acquired defects (see Fig. 28.11). More generally, plasma exchange has the practical advantage over plasma infusion of allowing larger amounts of plasma to be provided, avoiding the risk of volume overload, which may be of major concern in patients with kidney failure or cardiac dysfunction. The overall response rate to plasma exchange is 90% in recent series with FFP as replacement therapy. Patients who respond to plasma therapy usually have a good prognosis if the patient survives the acute episode.^{12,13} Infusion of cryosupernatant of plasma (i.e., plasma devoid of vWF multimers, fibrinogen, and fibronectin, which remain in the cryoprecipitate) may induce remission in patients who do not respond to repeated plasma exchanges with FFP.¹⁴ Patients who do not respond to plasma therapy usually have a very poor prognosis, but occasional responses to splenectomy or vincristine have been reported. However, the results of delayed splenectomy are possibly biased by selection of patients.

Most of these series, however, were reported before measurements of ADAMTS13 activity and autoantibodies were available. Thus, outcome data are difficult to interpret because patients with genetic or autoimmune disease were most likely considered together.

New Rationale for Established Treatments Better understanding of the pathogenetic mechanisms may help explain the heterogeneous responses to treatment in apparently similar diseases. Patients with genetically determined ADAMTS13 deficiency may benefit from both plasma infusion and exchange (with plasma replacement) because both may replace the defective activity. Those with immune-mediated deficiency benefit the most from the exchange procedure, which in addition to supplying fresh protease that may saturate the autoantibody activity may also remove the autoantibody from the circulation. The same considerations apply to the use of corticosteroids, vincristine, immunoglobulins, immunosuppressants, and splenectomy. Corticosteroids have yielded inconsistent results in patients with so-called idiopathic TTP. This is likely to be due to the fact that in immune

forms, these treatments may aim to inhibit the production of the autoantibody and, combined with plasma exchange, may result in effective clearance of the autoantibody from the circulation. On the contrary, they have no role in the treatment of genetic forms. Trials considering the two forms together invariably diluted the potential benefits of corticosteroids or immunosuppressive therapy in subjects with immune-mediated disease. Novel studies should probably focus on the role of corticosteroids as first-line therapy for immune-mediated forms and on vincristine, high-dose immunoglobulins, or other immunosuppressants as second-line therapy, with splenectomy considered as rescue therapy for those patients with refractory disease and life-threatening thrombocytopenia or neurologic involvement.

Rituximab, a humanized monoclonal antibody directed against the B-cell antigen CD20, induces a rapid and prolonged depletion of B cells that usually lasts 6 to 9 months. To date, more than 70 patients with severe TTP refractory to standard treatment have been treated with high response rates.¹⁵

Patients with TTP due to anti-ADAMTS13 autoantibodies have a high rate of relapse,¹⁶ and in recurrent cases, death and neurologic sequelae are common outcomes. The ideal treatment should retard or prevent relapses, but the response to these immunosuppressive treatments is variable and often inconclusive.¹⁷ Contrasting results have also been obtained with splenectomy.¹⁷

In patients who exhibited persistently undetectable ADAMTS13 activity and high titers of autoantibodies but who were in clinical remission, preemptive treatment with rituximab maintained remission for up to 29 months in three patients, whereas two relapsed after 51 and 13 months.¹⁸

Thrombotic Microangiopathy Associated with Genetic or Immune-Mediated Abnormalities of the Complement System

Factor H

Human glomerular endothelial cells and glomerular basement membrane (GBM) are rich in polyanionic molecules, which normally bind the factor H (FH) molecules deposited on their surface, providing an efficient shield against complement attack. Various mutations have been detected in the FH gene in familial cases of aHUS but also in patients with no familial history.¹⁹ The FH mutants are functionally inactive but normally secreted and detectable in immunoassays. Moreover, because not all patients have a persistent reduction in C3 levels, the diagnosis of FH-related aHUS cannot be excluded on the basis of normal C3 and FH serum concentrations. Genetic counseling of families with recognized genetic mutations allows the prenatal identification of affected offspring.

Plasma infusion or exchange has been used in patients with HUS and FH mutations, with the rationale of providing normal plasma FH activity.² Plasma exchange is first-line therapy during acute disease because defective FH may antagonize the function of normal FH provided with the infused plasma, and its removal may accelerate disease recovery. Weekly infusion of plasma may be required to raise FH plasma levels enough to maintain remission.² One patient regained normal renal function, and plasma therapy could be stopped after 1 year.²⁰ The rate of recurrence after kidney transplantation alone is 30% to 100%, occurring within 1 month after surgery in most cases. The role of simultaneous kidney and liver transplantation in such patients is discussed later.

Membrane Cofactor Protein

A rare cause of aHUS is a heterozygous mutation in membrane cofactor protein (MCP), a widely expressed transmembrane glycoprotein that regulates complement activation. MCP is highly expressed in the kidney and plays a major role in regulating glomerular C3 activation. When there is reduced expression of MCP, complement-activating stimuli may lead to microvascular cell damage. Fever accompanies the other clinical features of aHUS.²¹ The outcome is usually poor. Plasma infusion or exchange still remains a valid therapy that may have some effect.

As the graft has normal MCP expression, the risk of post-transplantation recurrence is logically expected to be negligible. Unexpectedly, of 10 MCP-mutated patients who received renal allografts with (theoretically) normal MCP, two had recurrences. One of these two patients probably had a mutation in another regulator of the complement alternative pathway, whereas in the other patient, endothelial microchimerism was proposed as the explanation of recurrence.²¹

Other Complement Factors

More than 30 cases of complement factor I (CFI) deficiency have been described since 1970.²² CFI is a plasma glycoprotein predominantly synthesized in the liver that inactivates C3b and C4b, prevents the formation of the C3 and C5 convertases, and thus inhibits the alternative and the classical complement pathways. The clinical signs often begin in early childhood and include increased susceptibility to recurrent infection, in particular with *Neisseria meningitidis* and *Streptococcus pneumoniae*. Plasma therapy appears to represent the most reasonable approach, although experience is very limited so far. Recurrence after kidney transplantation alone is extremely high; thus, combined liver-kidney transplantation seems preferable.²³

Additional genetic mutations have been recently associated with HUS, including heterozygous gain-of-function missense mutations in factor B and mutations in C3 factor. Moreover, rare cases of immune-mediated aHUS have been described. IgG antibodies to FH were detected in the plasma of three of 48 children with recurrent HUS after transplantation. FH plasma activity was decreased, whereas plasma FH antigenic levels and FH gene analysis were normal.²⁴

Screening and Diagnosis of Atypical Hemolytic-Uremic Syndrome In parallel with the improving understanding of the genetic basis of aHUS and its implications for patient management, in particular in the perspective of kidney transplantation for those who progress to ESRD, the demand for genetic screening has been progressively increasing. However, a full analysis for mutations in the four complement proteins so far recognized to be involved in the disease is extremely expensive and time-consuming. To optimize cost-effectiveness of genetic studies and to guarantee timely delivery of the results, an initial screen based on protein levels (either serum levels or surface expression) appears to be a rational approach for rapid identification of the likely gene involved (Fig. 28.12). When complement regulatory protein levels are normal, both the titer of anti-CFH antibodies and possibly involved genes should be studied according to the expected frequency of mutations. Thus, analysis should be considered first for the gene encoding CFH because it can be mutated in about 30% of cases, followed by the genes encoding MCP and CFI, which can be mutated in about 10% and 2% to 5% of cases, respectively. (For a list of laboratories performing the analyses, refer to reference 36.)

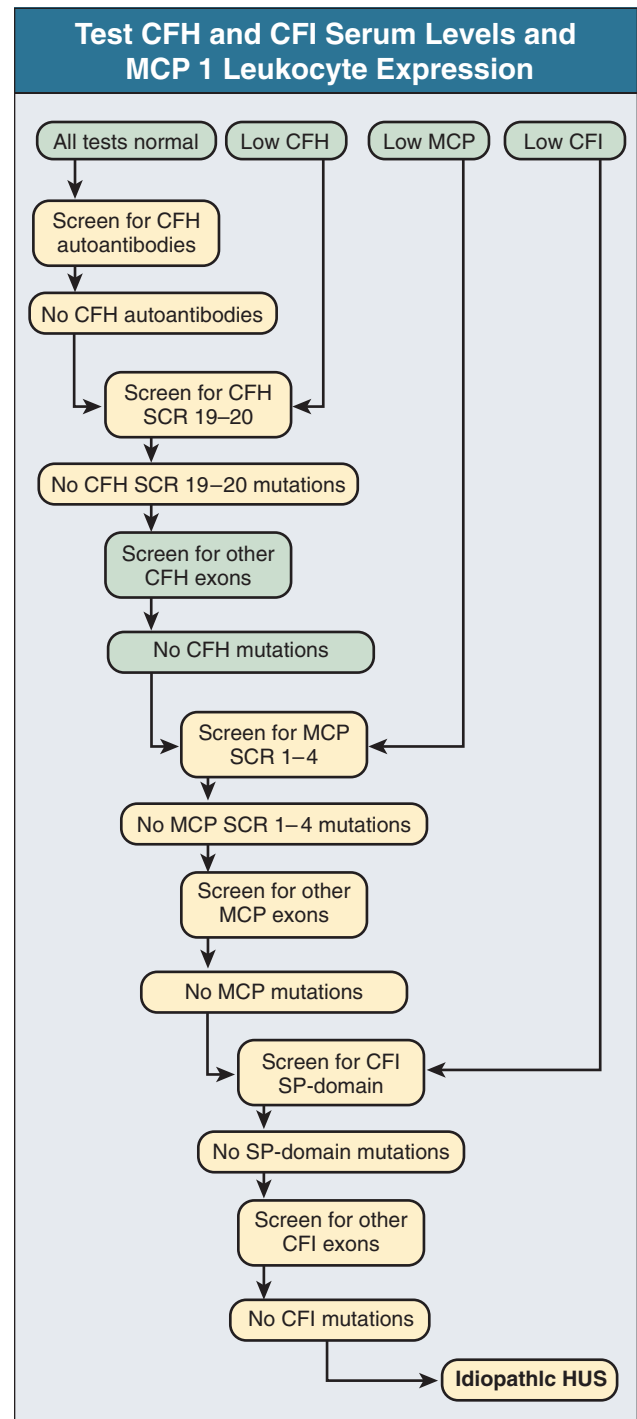

Figure 28.12 Flow diagram of the steps suggested to optimize the cost-effectiveness of screening for genetic defects in patients with non-Stx-associated HUS and genetically determined abnormalities in complement regulatory proteins. CFH, complement factor H; CFI, complement factor I; HUS, hemolytic-uremic syndrome; MCP, membrane cofactor protein; SCR, short consensus repeats. (From reference 25.)

Pregnancy-Associated Thrombotic Microangiopathy

TMA associated with pregnancy may be manifested as acute TTP; as hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome, a form of severe preeclampsia; or as HUS.²⁶ Pregnancy-associated TTP usually develops during the antepartum period. TTP occurs most likely before gestational week 28, when antithrombin III plasma activity is normal; preeclampsia most likely occurs after week 34 of gestation and is usually associated with decreased plasma antithrombin III activity. Plasma therapy has reduced maternal mortality rates to almost zero.²⁷ Delivery is recommended for those patients with pregnancy-associated TTP who do not respond to plasma therapy, and it is the treatment of choice for preeclampsia/HELLP syndrome. The role of other treatments often employed in idiopathic TTP remains unknown. When the disease persists, a course of plasma therapy is indicated. Between 28 and 34 weeks, the optimal treatment is controversial. Some authorities have held that delivery should always be considered first-line therapy, whereas others believe that a course of plasma therapy can be reasonably attempted before delivery is induced if there is no evidence of fetal distress and plasma antithrombin III activity is normal. There is no report of transmission of TTP to the infant.

HELLP Syndrome

In the HELLP syndrome, microangiopathic hemolysis and liver injury accompany hypertension and renal dysfunction. It is most common in white multiparous women with a history of poor pregnancy outcome. It usually occurs in the late third trimester, including the intrapartum period. On occasion, after an uncomplicated pregnancy, symptoms may also arise within 24 to 48 hours postpartum. Diagnosis is based on laboratory findings of hemolysis, elevated liver enzymes (serum aspartate transaminase >70 U/L), and low platelets (platelet count $<100 \times 10^3/\text{mm}^3$). An association with DIC is reported in 25% of cases. Intrahepatic hemorrhage, subcapsular liver hematoma, and liver rupture are rare but life-threatening complications. The maternal and perinatal mortality rates range from 0% to 24% and from 8% to 60%, respectively. Most of the perinatal deaths are related to abruptio placentae, intrauterine asphyxia, and extreme prematurity. As many as 44% of the infants are growth retarded. Delivery is the only definitive therapy. The therapy for hypertension and preeclampsia is discussed in Chapters 42 and 43. Both PD and hemodialysis (HD) have been used to treat AKI. Platelet transfusions are needed for clinical bleeding.

In approximately 5% of patients with HELLP syndrome, symptoms and laboratory abnormalities do not improve after delivery. These more often include CNS abnormalities associated with renal and cardiopulmonary dysfunction and activation of coagulation. Uncontrolled studies suggest that plasma exchange may help recovery in patients with persistent evidence of disease 72 hours or longer after delivery. Plasma therapy is ineffective during pregnancy and may increase fetal and maternal risk when it is used to delay delivery. Preliminary evidence suggested that corticosteroids may hasten disease recovery postpartum and postpone delivery and reduce the mother's need for blood products antepartum. However, the benefit of corticosteroids in postpartum HELLP syndrome was not confirmed in a randomized placebo-controlled trial of 105 women with postpartum HELLP syndrome. There was no difference in maternal morbidity, duration of hospital stay, need for rescue scheme, or use of blood products between the groups, nor was

there any difference with respect to the pattern of platelet counts, recovery, aspartate transaminase, LDH, hemoglobin, or diuresis.²⁸

Postpartum Hemolytic-Uremic Syndrome

Postpartum HUS is manifested within 6 months from normal delivery. The clinical course is usually fulminant. Supportive care, including dialysis, transfusions, and careful fluid management, remains the most important form of treatment. Whether plasma therapy improves survival or limits renal sequelae has not been established. Antiplatelet agents, heparin, and antithrombotic therapy may enhance the risk of bleeding and have no proven efficacy. Full recovery of renal function is very uncommon. The mortality rate ranged from 50% to 60%. Surviving patients have residual renal dysfunction and hypertension.

Systemic Disease–Associated Thrombotic Microangiopathy

Antiphospholipid Syndrome, Scleroderma, Hypertensive Emergencies

Plasma therapy should always be attempted in TMA associated with systemic diseases even though its efficacy is poorly defined.²⁹ In the antiphospholipid syndrome (see also Chapter 27), oral anticoagulation remains the only treatment of proven efficacy to prevent and to treat microvascular and macrovascular thrombosis, even if concomitant thrombocytopenia may increase the risk of bleeding. Preliminary reports suggest a potential efficacy of rituximab therapy, but further controlled studies are needed.³⁰ Blood pressure control is fundamental in TMA associated with scleroderma crisis and hypertensive emergencies.

Human Immunodeficiency Virus

HUS and TTP are both possible complications of acquired immunodeficiency syndrome (AIDS) that may account for as much as 30% of hospitalized TMA patients in cities where AIDS is epidemic.³¹ Plasma therapy is the only feasible approach in these forms, although the prognosis is poor. Uncontrolled series show that the survival rate of human immunodeficiency virus (HIV)–infected patients with TTP and without AIDS is comparable to that of idiopathic TTP.

Malignant Disease

Spontaneous TMA complicates almost 6% of cases of metastatic gastric carcinoma, which in turn accounts for about 50% of all malignant disease–associated TMA. The prognosis is extremely poor. Therapy is minimally effective. Administration of blood products to correct symptomatic anemia often results in exacerbation of the syndrome.^{1,2}

Drugs

Drugs associated with TMA³² include mitomycin C, ticlopidine, clopidogrel, quinine, interferon, CNIs, and estrogen-containing oral contraceptives (Fig. 28.13). Discontinuation of the offending drug is fundamental. The efficacy of plasma therapy is unclear; it seems ineffective with some drugs, such as mitomycin C, and very important with others, such as quinine.

Mitomycin and Anticancer Drugs TMA, more commonly resembling HUS, is described in 2% to 10% of cancer patients treated with mitomycin C. Renal dysfunction rarely occurs in patients given a cumulative dose lower than 30 mg/m². Patients who develop mitomycin C–associated TMA are usually in

remission from their malignant disease. The fatality rate is about 70%, and median time to death is about 4 weeks. Patients surviving the acute phase often remain on chronic dialysis or die later of recurrence of the tumor or metastases. The possibility of preventing the disease by giving corticosteroids during mitomycin treatment has been suggested and needs to be confirmed. Plasma exchange is usually attempted, but its effectiveness is unproven. Platinum- and bleomycin-containing combinations have also been reported to induce HUS.

Antiplatelet Drugs TMA occurs in one case per 1600 to 5000 patients treated with ticlopidine. Induction of autoantibodies against ADAMTS13 may be involved in the pathogenesis. Neurologic abnormalities dominate the clinical picture and usually occur within a few weeks of treatment. The overall survival rate is 67% and is improved by early treatment withdrawal and plasma therapy, which result in recovery of ADAMTS13 activity. Eleven cases have been reported during treatment with clopidogrel, mostly within 2 weeks of therapy.³³ All patients had neurologic involvement. After plasma exchange, most patients recovered. Half the patients were concomitantly treated with cholesterol-lowering drugs, and clinicians should be aware of this possible complication.

Quinine Quinine is one of the most common drugs associated with TMA.³⁴ It is generally used to treat muscle cramps but is also contained in beverages and nutrition health products

(e.g., tonic water, herbal preparations). TMA typically occurs in patients sensitized by prior exposure to quinine and rapidly follows re-exposure to the drug. Quinine-dependent platelet, erythrocyte, granulocyte, lymphocyte, and endothelial antibodies may contribute to the pathogenesis. Severe renal impairment is frequent, and HD is required in most cases. Recent outcome data show a high rate of death and chronic renal failure.³⁴ Quinine cessation and plasma therapy should be initiated rapidly. Avoidance of future quinine use is necessary.

Interferon Alfa TMA associated with interferon alfa is characterized by predominant renal impairment. Recovery of the disease is common in cases of early discontinuation of the drug and prompt supportive therapy. However, kidney prognosis is usually poor, with ESRD reported in about 42% of cases. The effectiveness of specific therapies, such as plasma exchange or infusion, is unknown.

Organ Transplantation–Associated Hemolytic-Uremic Syndrome

Post-transplantation HUS is reported increasingly.³⁵ In renal transplants, HUS may develop *de novo* after transplantation or may recur in patients whose primary cause of ESRD was HUS. Treatment of post-transplantation HUS is based on relief of symptoms, removal of the inciting factors, and plasma therapy. No other approach has proved effective.

De Novo Post-Transplantation Hemolytic-Uremic Syndrome

This form affects both renal and nonrenal transplant recipients and is usually triggered by immunosuppressive drugs, such as CNIs and OKT3, or less frequently by viral infections (HIV, parvovirus B19) and in renal transplant recipients by acute vascular rejection.³⁵ A particular form of *de novo* post-transplantation HUS may affect the recipients of a bone marrow transplant, usually in cases of graft-versus-host disease (GVHD) or of intensive GVHD prophylaxis, including total body irradiation. Drug withdrawal or dose reduction and plasma therapy achieved a high success rate (84%) in *de novo* cyclosporine- and tacrolimus-associated forms. A similar response rate, but in smaller studies, has been described with intravenous IgG infusion given with the rationale of neutralizing hypothetical circulating cytotoxic or platelet agglutinating factors. Once remission is achieved, possible immunosuppression treatments may include a decreased dose of cyclosporine or tacrolimus, a change from cyclosporine to tacrolimus or vice versa, and the avoidance of CNIs by use of mycophenolate mofetil or sirolimus. However, some cases of HUS have also been reported with sirolimus. Monoclonal anti-interleukin-2 receptor antagonists may also be a valid option to maintain adequate immunosuppression while avoiding the toxic effects of CNIs. The outcome of *de novo* forms occurring in the setting of viral infection is strongly influenced by the response to the treatment of the underlying disease. The outcome of *de novo* forms complicating bone marrow transplantation is very poor, with a mortality rate close to 90%.³⁵ In addition to the severity of HUS, infection, progressive GVHD, or relapse of the underlying disease may account for these discouraging outcomes.

Recurrent Post-Transplantation Hemolytic-Uremic Syndrome

Mutations in circulating complement factors H, I, B, and C3, all of which are mainly produced by the liver, will persist after kidney transplantation, resulting in post-transplantation recurrence in 80% of patients with mutations in the gene encoding

complement factor F or I. Recurrence rates in patients with complement factor B or C3 mutations are less well established.³⁶

Liver transplantation in addition to a renal allograft corrects the complement abnormality and prevents disease recurrence in such patients. Whereas this procedure appeared effective in preventing disease recurrence in early attempts, it was also associated with irreversible liver failure secondary to uncontrolled complement activation. Subsequently, the pivotal modification to avoid liver failure was to exchange large quantities of plasma before transplantation with further plasma supplementation during the procedure. This both increased the bioavailability of functional factor H during the critical period needed for the liver graft to recover synthetic functions and, at the same time, removed the endogenous mutant factor H, preventing possible antagonism of normal factor H supplied with plasma.³⁷ Patients also empirically received low-molecular-weight heparin (LMWH) and low-dose aspirin. Of the first seven patients treated this way, six patients were successfully treated and did not display any recurrence, whereas one died. At present, there is consensus that this procedure, with proper consideration of individual risks and benefits, offers the best opportunity for long-term transplant success.³⁶

Other less invasive treatment strategies to prevent recurrence of aHUS after kidney transplantation in patients with factor H mutations include intensified plasma exchange and C5 blockade. Intensive plasma exchange given before and long lasting after a single kidney transplantation and followed by chronic weekly plasma infusion³⁸ prevented HUS recurrences in five of six patients. Problems associated with chronic plasma treatment as well as the development of plasma resistance limit the feasibility of this approach.

Ecuzumab is a humanized monoclonal antibody against complement C5, thereby inhibiting its cleavage to C5a and C5b and preventing the generation of C5b-9. It has been approved for the treatment of paroxysmal nocturnal hemoglobinuria and displays an excellent safety profile.³⁹ Ecuzumab (Fig. 28.11) so far has been given to two patients with aHUS, one of them with recurrent aHUS in a renal allograft.^{39,40} In both, treatment resulted in reversal of hemolysis and partial recovery of renal function.^{39,40}

Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Nephropathy

Eberhard Ritz, Gunter Wolf

DEFINITIONS

Diabetic nephropathy (DN) is the leading cause of end-stage renal disease (ESRD) in most Western societies. It can develop in the course of both type 1 and type 2 diabetes and as a consequence of other forms of diabetes mellitus (DM).

Type 1 diabetes is an autoimmune disease characterized by antibody- and cell-mediated destruction of pancreatic islets. Type 1 diabetes may occur at any age but is common in childhood, usually presenting before the age of 30 years.

Type 2 diabetes is characterized by a combination of insulin resistance and insulin deficiency. The metabolic syndrome (insulin resistance, visceral obesity, hypertension, hyperuricemia, and dyslipidemia with high triglyceride levels and low amounts of high-density lipoprotein [HDL]) is often followed by type 2 diabetes. For a long period, insulin resistance is compensated by increased insulin secretion, but a gradual decline in pancreatic β -cell function finally culminates in hyperglycemia and ultimately insulin requirement in 40% to 50% of patients with type 2 diabetes. Type 2 diabetes was typically a disease of mostly elderly adults, but recently it is increasingly seen in adolescents and even in children. In addition, there are several other types of DM (e.g., different types of maturity-onset diabetes of the young, gestational diabetes, diabetes secondary to various metabolic disorders or the consequence of corticosteroid treatment).

PATHOGENESIS OF DIABETIC NEPHROPATHY

Genetic Factors

The risk of nephropathy is strongly determined by polygenetic factors, and only approximately 30% to 40% of patients with either type 1 or type 2 diabetes will ultimately develop nephropathy. The risk for development of DN is equal in type 1 and type 2 diabetes. The prevalence of nephropathy among diabetic patients varies between different racial and ethnic groups such that it is relatively increased in African Americans, Native Americans, Mexican Americans, Polynesians, Australian aborigines, and urbanized Indo-Asian immigrants in the United Kingdom compared with Caucasians. Although barriers to care seem likely to account for some of these interpopulation differences, genetic factors are also likely to contribute. Familial clustering of DN has been reported in both type 1 and type 2 diabetes and in both Caucasian and non-Caucasian populations. In a type 1 diabetic patient who has a first-degree relative with diabetes and nephropathy, the risk for development of DN is 83%. The frequency is only 17% if there is a first-degree relative with diabetes but

without nephropathy.¹ In type 2 diabetes, familial clustering has been well documented in Pima Indians,² and a familial determinant is also suggested by the observation that albumin excretion rates are higher in offspring of type 2 diabetic patients with nephropathy. The risk is particularly high in the offspring if the mother had been hyperglycemic during pregnancy, presumably because this causes reduced formation of nephrons (“nephron underdosing”) in the offspring,³ as shown in experimental studies.⁴ Low birth weight and nephron underdosing are also associated with hypertension, metabolic syndrome, and, although the data are somewhat controversial on this point, DN. The hypothesis has been proposed that nephron underdosing⁵ leads to compensatory glomerular hypertrophy and increased single-nephron glomerular filtration rate (GFR), thus aggravating glomerular injury if a renal insult such as diabetes occurs.

There is ongoing research to identify genetic loci for DN susceptibility through genomic screening and candidate gene approaches. The major problem is that there is no simple mendelian inheritance, and several genes are presumably involved. Whole genome scans searching the entire genome for chromosomal regions that are linked with DN identified several susceptibility loci, for example, on chromosomes 3q, 7p, and 18q. At present, the pathophysiologic function of such genetic regions is unknown. Gene polymorphisms may also contribute to familial clustering. A study suggested a genetic predisposition to DN due to a polymorphism in the carnosinase gene, causing accumulation of carnosine with antioxidant properties.⁶ Several studies also suggested some detrimental effect of the double deletion (DD) polymorphism of the angiotensin-converting enzyme (ACE) genotype on disease progression,⁷ although the finding has not been uniformly confirmed.^{8,9}

Hemodynamic Changes

Hyperfiltration is common in early diabetes but can be corrected with good glycemic control. Increased GFR involves glucose-dependent effects causing afferent arteriolar dilation, mediated by a range of vasoactive mediators (insulin-like growth factor 1 [IGF-1], transforming growth factor beta [TGF- β 1], vascular endothelial growth factor [VEGF], nitric oxide [NO], prostaglandins, and glucagon) (Fig. 29.1). Renal injury in DN is caused not only by hemodynamic disturbances (e.g., hyperfiltration, hyperperfusion) but also by disturbed glucose homeostasis, and the two pathways interact. For example, shear stress increases glucose transport into mesangial cells by upregulation of the specific glucose transporter. Furthermore, shear stress and mechanical strain resulting from altered glomerular

Figure 29.1 Schematic comparison of a normal nephron, a nephron in diabetic nephropathy (DN), and a nephron in DN after administration of angiotensin-converting enzyme (ACE) inhibitor/angiotensin receptor blocker (ARB). Note afferent vasodilation and efferent angiotensin II (Ang II)-mediated vasoconstriction in diabetes causing glomerular hypertension, which is relieved by ACE inhibitor/ARB treatment. Note also protein leakage into the filtrate and tubular loading with endocytosed protein causing an inflammatory reaction that promotes interstitial fibrosis. This is reversed by ACE inhibitor/ARB treatment.

hemodynamics trigger autocrine and paracrine release of cytokines and growth factors in the glomerulus.

There are also tubular abnormalities (e.g., increased tubular reabsorption of sodium). Hyperfiltration increases the colloid osmotic pressure in postglomerular capillaries, thus facilitating reabsorption of sodium in the proximal tubule. In the presence of hyperglycemia, increased proximal sodium reabsorption may also result from increased activity of the glucose-sodium cotransporter. Finally, there appears to be a role for angiotensin II (Ang II) causing hypertrophic proximal tubular growth and increased sodium reabsorption.¹⁰

Renal Hypertrophy

Renal growth is seen early after the onset of diabetes. The size of the kidney may increase by several centimeters. Glomerular enlargement is associated with an increase in the number of mesangial cells and of capillary loops, thus enhancing the filtration surface area. Enlargement of the glomeruli is the result of

cellular hypertrophy, whereas the tubular epithelial cells undergo both proliferation and hypertrophy.

In animal experiments, avoidance of hyperglycemia prevents renal hypertrophy. Elevated plasma glucose levels cause hypertrophy by stimulating growth factors in the kidney, including IGF-1, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), VEGF, TGF- β , and Ang II. The molecular mechanisms involved in glycemia-induced hypertrophy include induction of cell cycle inhibitors such as p27^{Kip1}. TGF- β stimulates protein synthesis (hypertrophy) but prevents cell proliferation and division by induction of cell cycle inhibitors. It is overexpressed in the glomeruli and the tubulointerstitium both in experimental and in human DN. Glucose as well as glucose-derived advanced glycation end products (AGEs) and Ang II stimulate the production of TGF- β in mesangial cells, podocytes, and tubular epithelial cells. Hyperglycemia also induces the expression of thrombospondin, a potent activator of latent TGF- β . Treatment of diabetic mice with neutralizing anti-TGF- β antibodies attenuated diabetes-related renal hypertrophy

and extracellular matrix accumulation and preserved renal function, but it had little influence on proteinuria. Similarly, inhibition of VEGF prevented glomerular hypertrophy in models of DN and also reduced albuminuria.

Mesangial Expansion and Nodule Formation

The hallmarks of DN are mesangial expansion, nodular diabetic glomerulosclerosis (the acellular Kimmelstiel-Wilson lesion), and diffuse glomerulosclerosis. The early mesangial lesion is characterized by a variable increase in mesangial cell number and size associated with an increased deposition of extracellular matrix. In later stages, a general loss of mesangial cells occurs. Increasing evidence suggests that local NO deficiency contributes to these histologic lesions, in particular nodule formation. Indeed, endothelial cell nitric oxide synthase (NOS)-deficient mice made diabetic with streptozotocin represent one of the most promising models for DN.

Mesangial expansion is mediated by both glucose and glucose-derived AGEs. In experimental models, mesangial changes can largely be prevented by tight glycemic control or the use of AGE inhibitors such as aminoguanidine. The effects are presumably mediated by TGF- β .

Inflammation and Diabetic Nephropathy

Inflammatory processes and immune cells are involved in the development and progression of DN.¹¹ Glomerular and interstitial infiltration by monocytes-macrophages and activated T lymphocytes is observed both in human biopsy specimens and in animal models of DN. An inflammatory state is also suggested by the common elevation of serum levels of acute-phase proteins and elevated neutrophil counts. Chemokines and their receptors, in particular monocyte chemoattractant protein 1 (MCP-1/CCL2), as well as adhesion molecules seem to contribute to this.¹¹ Possibly fractalkine/CX3CL1 functions as an arrest chemokine in monocyte-macrophage adhesion before migration into the kidney. T-lymphocyte recruitment is the consequence of glomerular and tubulointerstitial upregulation of RANTES/CCL5 structures as well as tubulointerstitial upregulation of IP-10/CXCL10 (Fig. 29.2).

Mechanisms Underlying Proteinuria

Widening of the glomerular basement membrane (GBM) is associated with accumulation of type IV collagen and net reduction in negatively charged heparin sulfate. However, the latter cannot be the key factor underlying proteinuria as selective reduction of GBM proteoglycans unexpectedly reduced rather than increased proteinuria.¹² This supports the notion that the podocyte is more important in the genesis of proteinuria.¹² Biopsies in patients with DN documented a correlation between the degree of proteinuria and podocyte pathology, specifically the width of the foot processes. The expression of one permeability-controlling protein, nephrin, is abnormally low in DN.¹² The transcription of nephrin is suppressed by Ang II and restored by inhibitors of the renin-angiotensin system (RAS). In addition, in DN, apoptosis of podocytes is triggered by various factors including Ang II and TGF- β . Finally, migration of podocytes is reduced by AGE-induced suppression of neuropilin 1, preventing surviving podocytes from covering denuded areas of basement membrane, thus causing formation of synechia and development of focal glomerulosclerosis (FSGS).

Figure 29.2 Activated nuclear factor (NF)- κ B and overexpression of related chemokines in human diabetic nephropathy (DN). Overexpression of chemokines (MCP-1, RANTES), osteopontin (OPN), and activated NF- κ B in human DN (**a**, normal, non-diabetic kidney; **b-h**, DN) indicating the inflammatory nature of DN. α -SMA, α -smooth muscle actin. (From reference 13.)

There is crosstalk between glomerular endothelial cells and podocytes, and this involves activated protein C (APC). APC formation is regulated by endothelial thrombomodulin and is reduced in diabetic mice.¹⁴ In DN, thrombomodulin-dependent APC formation inhibits podocyte apoptosis (Fig. 29.3).¹⁴

In cultured podocytes, adiponectin administration reduced the permeability to albumin and caused podocyte dysfunction. Because adiponectin levels are low in patients with the metabolic syndrome or type 2 diabetes, lack of adiponectin may further contribute to proteinuria.

In advanced stages of DN, high-molecular-weight serum proteins are able to escape across basal membranes with disrupted texture, gaps, and holes (nonselective proteinuria).

Tubulointerstitial Fibrosis and Tubular Atrophy

Tubulointerstitial pathology is seen early¹⁵ in DN and correlates with prognosis. The pathomechanisms underlying tubulointerstitial fibrosis and tubular atrophy are similar to or identical with those in nondiabetic progressive renal disease (see Chapter 75): release of growth factors, in particular TGF- β , and other cytokines from the glomerulus and direct or indirect effects of proteinuria. Under the influence of mediators such as TGF- β and

Figure 29.3 Crosstalk between endothelial cells and podocytes involving protein C. Under physiologic conditions, protein C is activated by the binding of thrombin to its receptor, called thrombomodulin, on glomerular endothelial cells. The formed complex catalyzes the conversion of protein C to its catalytically activated form, which has potent anticoagulant, profibrinolytic, anti-inflammatory, and cytoprotective effects. In diabetic nephropathy (DN), the production of activated protein C in the glomerulus is reduced because of suppression of thrombomodulin expression. Decreased functional activity of activated protein C affects the permeability of the glomerular capillary wall and enhances apoptosis of glomerular endothelial cells and podocytes. (From reference 16.)

Ang II, tubular cells change their phenotype and become fibroblasts.¹⁴ High glucose concentration and AGEs further stimulate this process. Proapoptotic genes are expressed by tubular cells in DN, and this is promoted by Ang II.

Clinical studies provided evidence that even mild anemia (hemoglobin level <13.8 g/dl) increases the risk of progression of DN. Treatment of anemia early in renal failure with erythropoietin (EPO) may slow the decline of renal dysfunction in DN. Anemia presumably causes renal hypoxia.¹⁵ Moreover, hypoxia is further amplified by the progressive hyalinosis of the afferent and efferent arterioles and loss of peritubular capillaries.¹⁷ In experimental models of chronic renal injury, hypoxia is an important factor aggravating interstitial fibrosis, partly by the induction of factors such as TGF- β and VEGF. The transition of tubular epithelial cells into fibroblasts is stimulated by cellular hypoxia. The induction of growth factors and cytokines is mediated by hypoxia-inducing factor 1, and Ang II can aggravate this.

Hyperglycemia and Diabetic Nephropathy

Role of Glucose Control

Evidence of the role of tight glycemic control in retarding the development of DN includes the following:

- Studies suggest that with good glycemic control (reflected by an average HbA_{1c} level of 7.0%), only 9% of type 1 diabetic subjects will develop ESRD after 25 years as opposed to the historical prevalence of 40%.¹⁸

- Results from the Diabetes Control and Complications Trial (DCCT) showed a remarkable reduction in progression from normoalbuminuria to microalbuminuria and other microvascular complications, specifically retinopathy, in patients with type 1 diabetes with tight glycemic control.¹⁹ At least for cardiovascular (CV) sequelae, the benefit of early aggressive reduction of glycemia persisted despite later deterioration of the glycemic control.²⁰
- Euglycemia that followed isolated transplantation of the pancreas was associated with a regression of the diabetic glomerulosclerosis after 10 years.²¹
- Evidence from the United Kingdom Diabetes Prospective Study (UKPDS) showed that reducing the HbA_{1c} level by ~0.9% in subjects with type 2 diabetes reduces the risk for development of microvascular complications, including nephropathy.²²
- The ADVANCE study randomly assigned 11,140 patients with type 2 diabetes to either intensive glucose control or standard glucose control. At the end of follow-up of 5 years, the HbA_{1c} level was 6.5% in the intensive group and 7.3% in the standard therapy group. Intensive glucose control was associated with a significant reduction in renal events and new-onset microalbuminuria. The trial did not show a significant effect of intensive control on major macrovascular events.²⁴

The mechanisms by which hyperglycemia induces DN are complex and may involve not only effects of elevated glucose

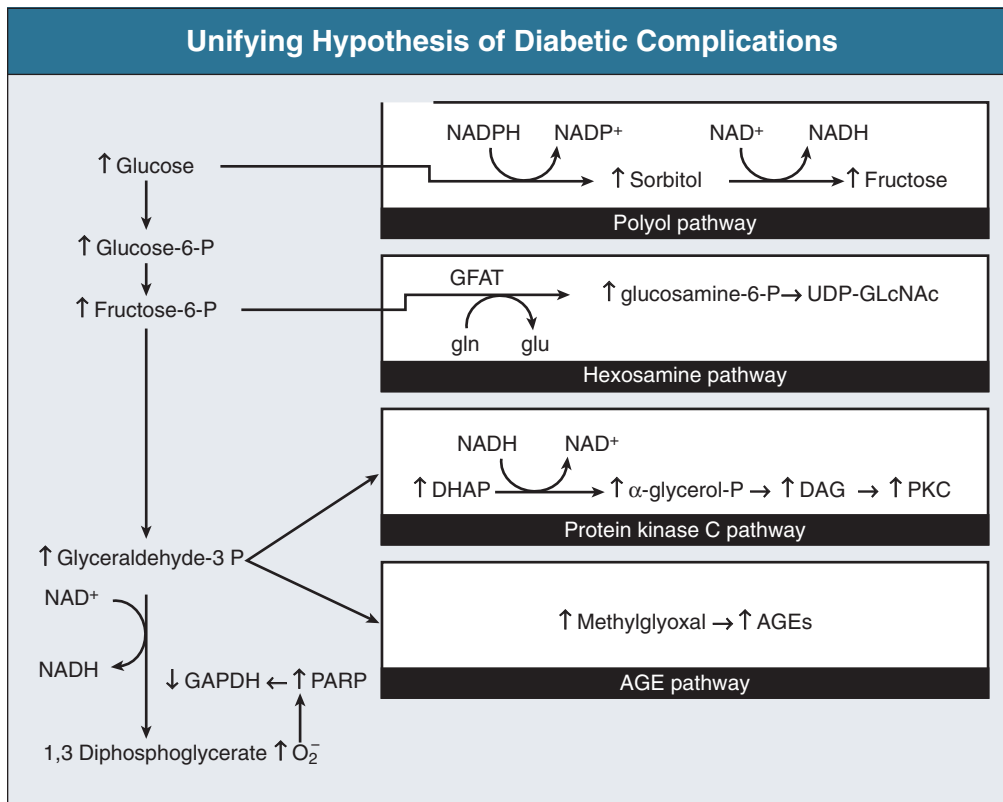

Figure 29.4 Unifying hypothesis of diabetic complications. Mitochondrial overproduction of superoxide activates four major pathways of hyperglycemic damage by inhibiting GAPDH. DHAP, dihydroxyacetone phosphate; DAG, diacylglycerine (an activator of protein kinase C, PKC, and of triose phosphates to methylglyoxal), the main intracellular advanced glycation endproduct (AGE) precursor. Increased flux of fructose-6-phosphate to UDP-N-acetylglucosamine increases modification of proteins by O-linked N-acetylglucosamine (GlcNAc) and increased glucose flux through the polyol pathway consumes nicotinamide adenine dinucleotide phosphate (NADPH) and depletes glutathione (GSH). NAD, nicotinamide adenine dinucleotide; UDP, uridine diphosphate; GAPDH, glyceraldehyde-3-phosphate-dehydrogenase; GFAT, glutamine fructose-6-phosphate amidotransferase; gln, glutamine; glu, glutamic acid; PARP, poly [ADP-ribose] polymerase; P, phosphate. (From reference 23.)

levels *per se* but also the generation of AGEs and alcohol sugars (polyols) as a consequence of hyperglycemia.

Brownlee proposed a unifying mechanism of how hyperglycemia leads to diabetic complications including DN (Fig. 29.4). An increase in intracellular glucose concentrations stimulates glucose oxidation in the tricarboxylic acid cycle, pushing more electron donors (NADH, FADH₂) into the electron transport chain.²⁵ When a critical threshold is reached and electrons are donated to molecular oxygen, superoxide is generated. This mitochondrial overproduction of superoxide activates four major pathways that are involved in DN.

Protein Kinase C (PKC) Pathway Many of the adverse effects of hyperglycemia have been attributed to activation of PKC, a family of serine-threonine kinases that regulate diverse vascular functions. The activity of PKC, especially the membrane-bound form, is increased in the retina, aorta, heart, and glomeruli of diabetic animals. In short- and long-term studies of diabetic rats, an orally effective PKC- β -selective inhibitor ameliorated glomerular hyperfiltration, albuminuria, and renal TGF- β overexpression as well as extracellular matrix accumulation. PKC- α may represent an additional therapeutic target because albuminuria was virtually absent in diabetic PKC- α knockout mice.

Advanced Glycation End Products Pathway Chronic hyperglycemia can lead to nonenzymatic glycation of amino acids and proteins (Maillard or browning reaction) (Fig. 29.5).²⁶ Over time, these products undergo rearrangement, including cross-linking, to become irreversible AGEs. Both circulating and tissue proteins as well as lipids and nucleic acids may thus be glycated. Although primarily observed in diabetes, AGEs also accumulate in aging and in renal failure.²⁶

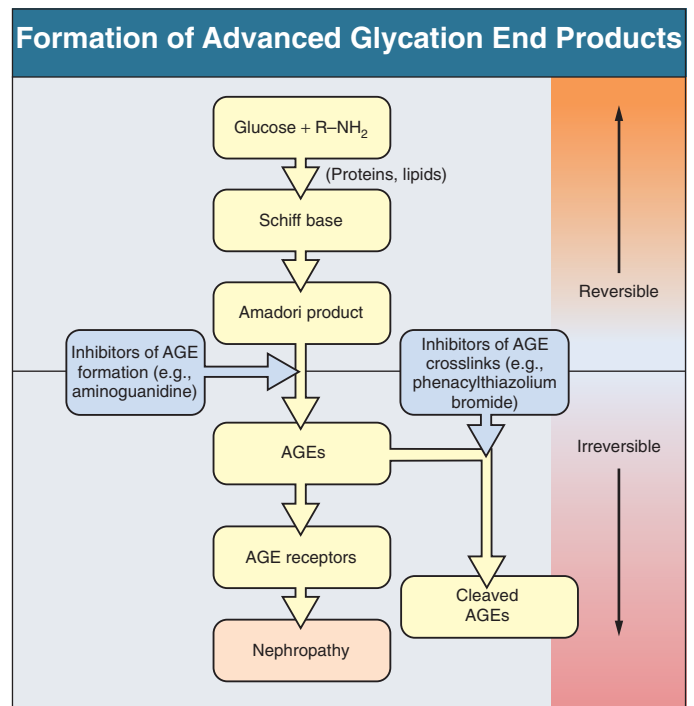

Figure 29.5 Mechanism of formation of advanced glycation end products (AGEs).

The concentration of AGEs is increased in the sera of DN patients. AGEs have also been localized to diabetic glomeruli by immunohistochemistry. AGEs bind to a variety of cell types, including macrophages and mesangial cells. They mediate a variety of cellular actions, including expression of adhesion molecules, cell hypertrophy, extracellular matrix synthesis, epithelial to mesenchymal transition, and inhibition of NOS. AGEs injected *in vivo* induce albuminuria and glomerulosclerosis.²³ AGEs have profound effects on podocytes, including induction of hypertrophy followed by apoptosis and suppression of nephrin synthesis. Among several binding sites, the most important is the putative receptor RAGE (receptor for AGE), a pattern recognition receptor. It is present in tubular cells and podocytes. Ang II stimulates upregulation of RAGE on podocytes.²⁷ This effect is mediated by angiotensin₂ (AT₂) receptors not blocked by sar-tanes.²⁷ One of the actions of RAGE is activation of nuclear factor (NF)- κ B. sRAGE, the soluble extracellular domain of RAGE, acts as a decoy receptor and experimentally ameliorates the renal lesions in diabetes.²⁸

Administration of aminoguanidine, an inhibitor of AGE formation, to animals with diabetes reduces AGE deposition, mesangial matrix expansion, and albuminuria but has inconsistent effects on GBM thickening. Preliminary clinical studies suggest beneficial effects on retinopathy, lipids, and proteinuria. The clinical experience with this compound has been disappointing and riddled with side effects. Newer, more specific agents have been developed that may be more potent blockers of AGE formation. Phenacylthiazolium bromide is a novel compound that cleaves covalent, AGE-derived protein cross-links and provides a conceptual basis for the reversal of AGE-mediated tissue damage, which until now has been regarded as irreversible.

Polyol Pathway The role of polyols in diabetic complications has been assessed with aldose reductase inhibitors, such as sorbinil, tolrestat, and ponalrestat. They have shown promise in preventing diabetic cataracts and improving or stabilizing diabetic neuropathy. Aldose reductase inhibitors also blunt hyperfiltration and have a mild effect on reducing albuminuria in both experimental and human diabetes. However, overall, the experience of treatment with aldose reductase inhibitors in DN has been disappointing, and treatment was associated with hypersensitivity reactions and liver function abnormalities.

Hexosamine Pathway Although most of the intracellular glucose is metabolized by the glycolytic pathway, some fructose 6-phosphate is diverted into the hexosamine pathway, increasing the concentrations of *N*-acetylglucosamine. This glucosamine modifies certain transcription factors, such as Sp1 activity, by post-translational *O*-linked glycosylation. In turn, Sp1 then leads to enhanced transcription of key mediators, such as TGF- β 1 and plasminogen activator inhibitor 1. Glucosamine-mediated modification of the enzyme Akt/PKB reduces expression of endothelial NOS and promotes apoptosis of cells.

Renin-Angiotensin-Aldosterone System and Diabetic Nephropathy

Studies in patients with type 1 and type 2 diabetes as well as in various animal models of diabetes suggest that ACE inhibitors or angiotensin receptor blockers (ARBs) retard progression of DN (see Chapter 30).

Although plasma renin activity is low in DN, it is inappropriate in relation to increased extracellular volume and exchange-

able sodium, suggesting activation of the RAS.²⁹ This has raised the possibility that activation of the intrarenal RAS may play a critical role in the development of DN. In experimental diabetes, sites of local RAS activation have been identified in glomeruli (podocytes, mesangial and endothelial cells), renal vessels, and tubular cells.^{28,29} High glucose concentration and AGEs stimulate angiotensinogen and renin expression in various renal cells, mainly through reactive oxygen species. Proteinuria further activates the local RAS of tubular cells. A new mechanism of how high levels of glucose directly trigger the release of renin involves local accumulation of succinate and activation of the kidney-specific G protein-coupled metabolic receptor GPR91.³⁰ Adipocytes are another source of Ang II in obese patients.

In patients with DN, prorenin levels are elevated, possibly reflecting increased synthesis.³¹ Specific prorenin and renin receptors have been demonstrated in the kidney³¹; ligand binding causes nonenzymatic activation of prorenin to yield renin activity and locally produced Ang II.³¹ Moreover, prorenin as well as renin can directly bind to specific receptors on mesangial and tubular cells and induce proinflammatory and profibrogenic cytokines. Further complexity is introduced by the observation that in diabetes, chymase is strikingly expressed in the kidney; this enzyme generates Ang II but is not inhibited by ACE inhibitors.³² On the other hand, the enzyme ACE2 generates peptides such as angiotensin 1-7, which antagonize the effects of Ang II.²⁸ ACE2 activity is reduced in DN, leading to a decrease in angiotensin 1-7 and further amplification of the effects of Ang II. Interestingly, 1,25-dihydroxyvitamin D₃ suppresses the RAS. Thus, in diabetics with advancing chronic kidney disease (CKD), decreasing calcitriol production further activates the RAS.

Ang II has many nonhemodynamic effects and mediates cell proliferation, hypertrophy, matrix expansion, and cytokine (TGF- β , VEGF) synthesis.²⁹ Therefore, ACE inhibitors and ARBs presumably act by hemodynamic as well as by nonhemodynamic actions.

Aldosterone accelerates progression in renal damage models independently of Ang II. In DN, aldosterone escape has been linked to progression of proteinuria (see Chapter 30). Aldosterone synthesis is stimulated in DN, and this steroid hormone stimulates the synthesis of other proinflammatory and profibrogenic cytokines (MCP-1, TGF- β).

Other vasoactive agents may also be involved in the pathogenesis of DN, including alterations in systemic or intrarenal production of endothelin, NO, the kallikrein-kinin system, and natriuretic peptides.

Uric Acid and Fructose

Experimental and clinical studies have suggested that uric acid may contribute to the development of hypertension and kidney disease. Uric acid stimulates mitogen-activated kinases (p38 and ERK) and nuclear transcription factors (NF- κ B and activator protein [AP] 1), resulting in PDGF-dependent proliferation, cyclooxygenase 2-dependent thromboxane production, MCP-1 and C-reactive protein synthesis, and stimulation of Ang II in renal cells.³³ Clinical studies indicate that uric acid level early after onset of type 1 diabetes is independently associated with the risk for later development of DN.³⁴

It has been proposed that excessive fructose intake (>50 g/day) may be one of the underlying causes of metabolic syndrome and type 2 diabetes. The primary sources of fructose are sugar (sucrose) and high-fructose corn syrup. The ingestion of excessive fructose induces features of metabolic syndrome in both

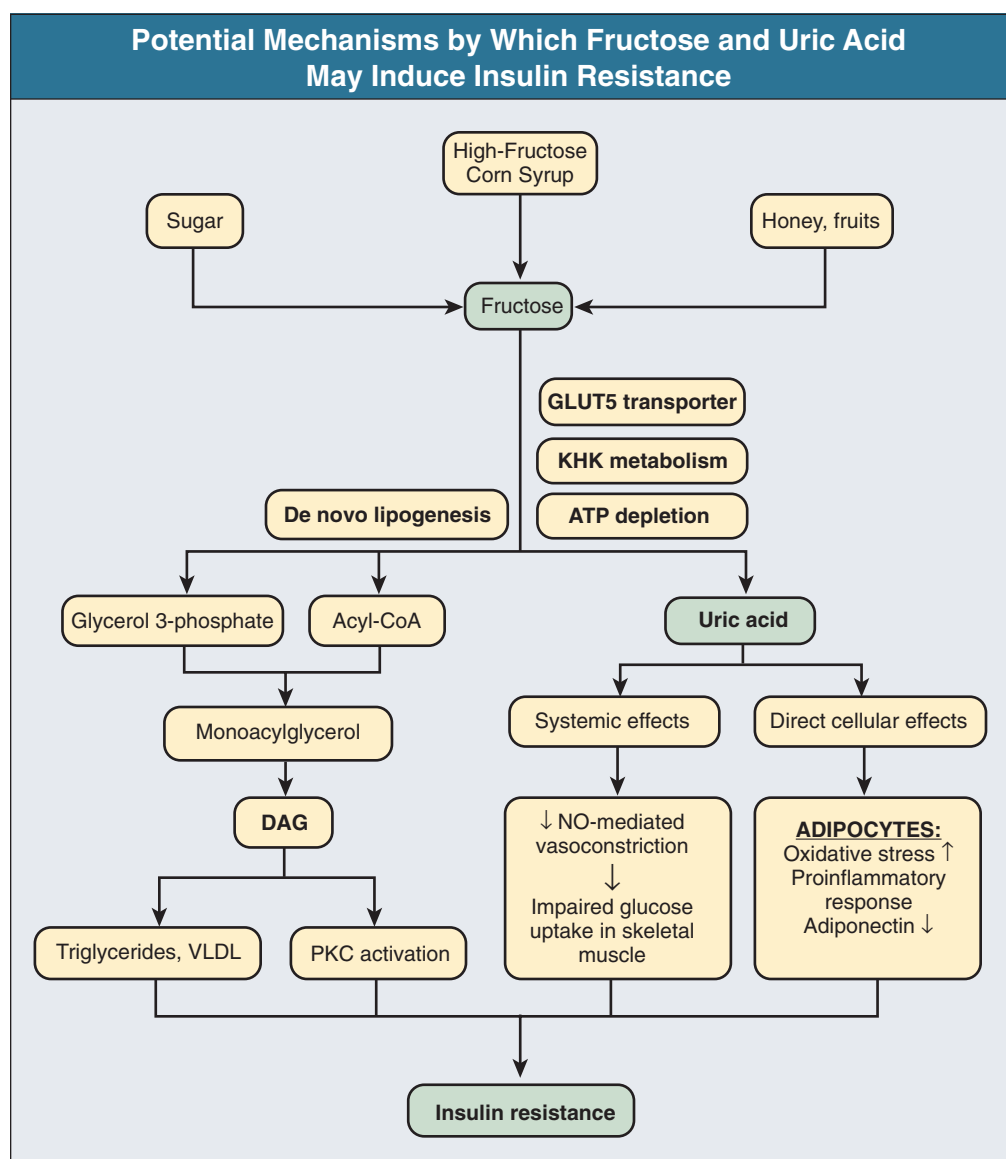

Figure 29.6 Potential role of fructose and uric acid in mediating insulin resistance. Fructose enters the cell through the GLUT5 transporter and is metabolized by fructokinase (ketohehexokinase [KHK]). As part of this metabolism, ATP depletion may occur, generating uric acid with systemic effects that block insulin-dependent nitric oxide (NO)-mediated vascular dilation as well as direct cellular effects on the adipocyte. Fructose also causes *de novo* lipogenesis, which can lead to intracellular triglycerides that can also induce insulin resistance. ATP, adenosine triphosphate; DAG, diacylglycerol; HFCS, high-fructose corn syrup; PKC, protein kinase C; VLDL, very low density lipoprotein. (From reference 30.)

laboratory animals and humans. Interestingly, fructose appears to mediate the metabolic syndrome in part by raising uric acid.³³ Fructose and uric acid also mediate insulin resistance (Fig. 29.6). Thus, excessive fructose intake in concert with uric acid may foster the development and progression of DN.

EPIDEMIOLOGY

In most Western countries, DN has become the leading cause of ESRD. According to the U.S. Renal Data System (www.USRDS.org), in 2006, DN was the most frequent primary diagnosis with 159 per million population per year. The proportion of diabetics among patients with ESRD varies considerably between countries but had consistently been on the rise in all countries until recently, when the incidence figures have stabilized. In patients admitted for renal replacement therapy (RRT), we found diabetes in 49%, but classic features of DN were observed in only 60% of these (i.e., large kidneys, proteinuria exceeding 1 g/24 h with or without retinopathy); 13% exhibited an atypical presentation with ischemic nephropathy,

and in 27% of the cases, a known primary renal disease (e.g., polycystic kidney disease [PKD], analgesic nephropathy, glomerulonephritis [GN]) coexisted with diabetes.³⁵ An important mode of presentation has become irreversible acute kidney injury (AKI), for example, after administration of radiocontrast media, cardiac events, and septicemia. Often, the diagnosis of diabetes had not been made at the time of admission because hyperglycemia may disappear when patients lose weight secondary to anorexia from renal failure (so-called DN without diabetes). This may explain why at least 5% of patients develop apparent *de novo* diabetes after the start of dialysis.

The great majority (in our experience, >90%) of patients entering ESRD with diabetes as a comorbid condition suffer from type 2 diabetes. In the past, few type 2 diabetic patients had a chance to live long enough to develop nephropathy. Today, with better treatment of hypertension and of coronary heart disease, an increasing proportion of type 2 diabetic patients survive and are exposed to the risk for development of DN and ESRD. The proportion of type 1 and type 2 diabetic patients who develop proteinuria and elevated serum creatinine concentration is related

Figure 29.7 Cumulative risks for development of proteinuria and progression to renal failure in patients with type 1 and type 2 diabetes. (From reference 35.)

Figure 29.8 Predicted increase in diabetes prevalence. Number of patients by age group, region (developing versus developed countries), and year. (From reference 39.)

to the duration of diabetes. As shown in Figure 29.7, the cumulative risks for development of proteinuria and progression are practically superimposable in type 1 and type 2.³² Diabetes-related deaths amounted to almost 3 million, equivalent to 5% of world all-cause mortality in 2000. There is a major increase in the prevalence of type 2 diabetes in the developing world compared with the developed world (Fig. 29.8). For example, in Asia, the excess death from diabetes is most prominent in the age group between 50 and 60 years, which translates to a reduction in life expectancy of more than a decade. Up to 60% of Asian diabetic patients have microalbuminuria or macroalbuminuria, compared with 30% to 40% reported in Western diabetic populations in cross-sectional surveys.³⁶ One explanation for this ethnic disparity in renal risk may be that longer survival in Asians provides greater opportunity for the evolution of renal complication. In addition, several polymorphisms have been discovered to independently predict DN in Chinese patients.³⁷

There is also a difference in the incidence of diabetes-associated ESRD in Western countries, with very high numbers of patients in the United States.³⁸ The reasons for this fact are certainly complex and may include genetic variability, differences in lifestyle, different national health systems with variable access to screening programs, and other factors.⁴⁰ A targeted screening program may help in the early identification of individuals at high risk for DN.³⁸

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

DN constitutes part of a generalized microvascular syndrome that is accompanied by macrovascular disease.

Obesity, The Metabolic Syndrome, and Renal Disease

The metabolic syndrome—defined as having at least three of the five parameters of increased waist circumference, elevated triglycerides, decreased high-density lipoproteins, elevated blood pressure, and elevated fasting blood glucose concentration—is increasingly being recognized not only as a major contributor to cardiovascular diseases but also as an influence on renal function. The recognition that the metabolic syndrome is strongly associated with kidney disease has been appreciated only recently.⁴¹ Obese individuals (body mass index >30) have large kidneys and glomerulomegaly. These patients have increased renal blood flow, increased filtration fraction, and glomerular hyperfiltration.⁴² Obese patients exhibit microalbuminuria even in the absence of concomitant hypertension. The resemblance of obesity-related kidney disease to the early features of diabetic kidney disease is striking. In addition, sleep apnea, which is common in obese individuals, leading to hypoxic episodes, may

also contribute to kidney impairment. Visceral adipocytes are a potent source of deleterious factors⁴³ that could have an impact on renal function (Ang II, leptin, tumor necrosis factor [TNF] α). Thus, renal changes may occur years before the manifestation of type 2 diabetes during obesity and the development of the metabolic syndrome.

Evolution of Diabetic Nephropathy

One of the earliest changes of renal function in diabetes is an increase in GFR, or hyperfiltration, which is observed in patients with type 1 and also many with type 2 diabetes. It is paralleled by an increase in renal size. The next observable change is the development of albuminuria. Somewhat arbitrarily, albumin excretion rates between 0 and 30 mg/day are called normoalbuminuria, and between 30 and 300 mg/day, microalbuminuria. Diabetic patients with persistent microalbuminuria are at markedly increased risk for development of overt DN, which is heralded by the development of proteinuria (albuminuria >300 mg/day), on average 15 years after disease onset, with progressive increase in proteinuria and BP as well as development of progressive CKD.

Mogensen⁴⁴ proposed a scheme of the different stages of DN (Fig. 29.9) that is valid in type 1 diabetes but less reliable in type 2 diabetes, in which CKD may occur in the absence of microalbuminuria, possibly the result of microvascular disease.

Hypertension and Diabetic Nephropathy

If hypertension develops in a patient with type 1 diabetes, it is almost always of renal parenchymal origin. However, today, type

1 diabetics survive longer, and a minority of elderly type 1 diabetics develop primary hypertension with no evidence of nephropathy. In patients with type 2 diabetes, hypertension often precedes the onset of diabetes by many years and decades as a feature of the metabolic syndrome. At the time when type 2 diabetes is diagnosed, an abnormal BP and an abnormal circadian BP profile are found in 80% of patients. Prediabetic hypertension increases the risk of onset and progression of DN. If patients with type 2 diabetes ultimately develop nephropathy, the prevalence of hypertension increases further and the degree of BP elevation is greater, but the relationship between hypertension and nephropathy is generally much less close than in type 1 diabetes. The pathogenesis of hypertension in type 2 diabetes is complex and involves activation of the RAS, direct sympathetic activation, and macrovascular changes.⁴⁵ Furthermore, there is evidence that genetic factors defining primary hypertension as well as diabetes are clustered (Fig. 29.10).

In DN, it has been well documented that the nocturnal BP decrease is frequently attenuated (nondipping), and nondipping even precedes the onset of microalbuminuria.⁴⁶ Furthermore, the BP response to exercise tends to be exaggerated, even when the BP is normal under basal conditions. Diminished compliance of the central arteries with stiffening of the aorta increases the peak systolic pressure and decreases the diastolic pressure, resulting in increased BP amplitude. The great BP amplitude explains why isolated systolic hypertension is so common in patients with type 2 diabetes.⁴⁷ Low diastolic pressure increases the risk of coronary events because coronary perfusion occurs during diastole only. Ambulatory pulse pressure and impaired nocturnal BP decline are independent predictors of nephropathy progression in type 2 diabetic patients (Fig. 29.11).

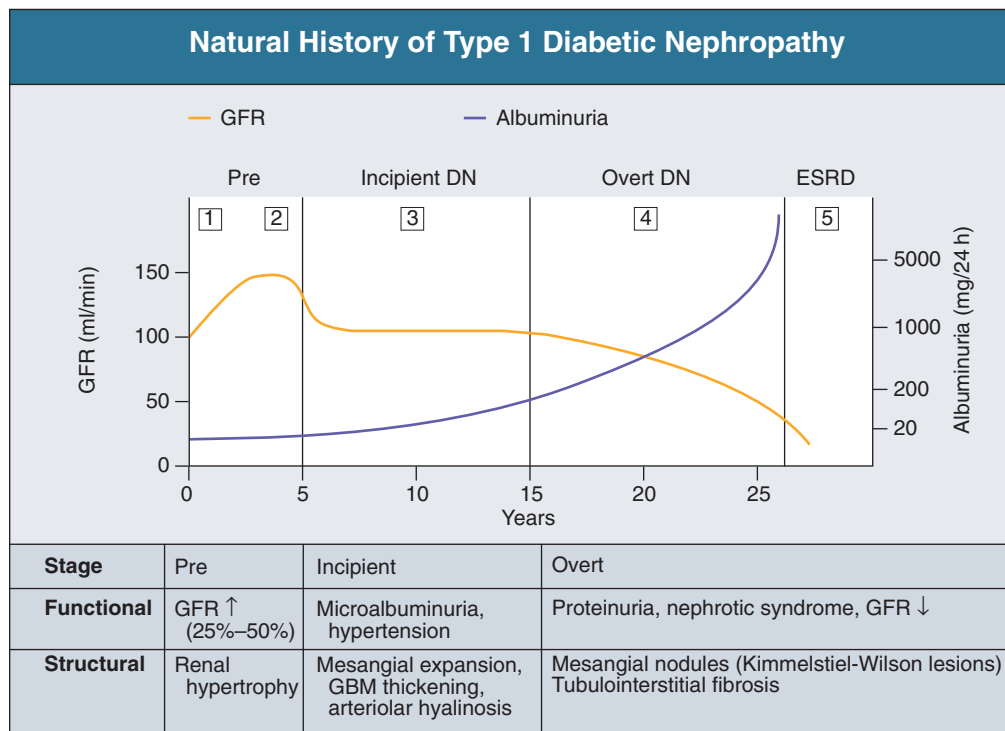

Figure 29.9 Natural history of type 1 diabetic nephropathy (DN). Functional and structural manifestations of DN. Numbers 1 through 5 indicate the stages of nephropathy defined by Mogensen. DN, diabetic nephropathy; ESRD, end-stage renal disease; GBM, glomerular basement membrane; GFR, glomerular filtration rate. (From reference 44.)

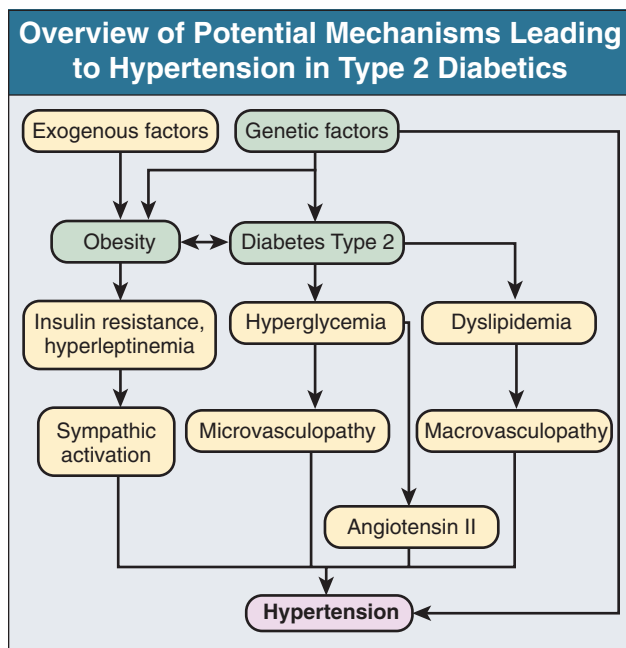

Figure 29.10 Overview of potential mechanisms leading to hypertension in type 2 diabetics. Genetic susceptibility factors for primary hypertension and diabetes may be clustered so that an individual patient may have a higher incidence of both diseases. Obesity and the metabolic syndrome lead to insulin resistance and hyperleptinemia associated with sympathetic nerve activation. Hyperglycemia directly activates the renin-angiotensin system (RAS) and, in addition, through renal microvasculopathy stimulates development of hypertension. Dyslipidemia leads through macrovasculopathic alteration to stiffness of vessels and hypertension.

Extrarenal Microvascular and Macrovascular Complications Associated with Diabetic Nephropathy

Diabetic retinopathy is present in virtually all patients with type 1 diabetes and nephropathy. In contrast, only 50% to 60% of proteinuric patients with type 2 diabetes suffer from retinopathy.⁴⁸ Consequently, the absence of retinopathy does not exclude the diagnosis of DN in patients with type 2 diabetes.⁴⁹ The risk of blindness because of severe proliferative retinopathy is substantially higher in diabetic patients with nephropathy, but it has become rare today with better ophthalmologic care. In patients with DN, retinopathy tends to progress more rapidly so that yearly or half-yearly ophthalmologic examination is indicated.

Many patients with DN also have polyneuropathy. Sensory polyneuropathy is an important aspect of the “diabetic foot.” There is a strong inverse correlation between the incidence of diabetic foot and renal function (Fig. 29.12).⁵⁰ Motor and sensory neuropathy may cause areflexia, wasting, and sensory disturbances such as paresthesia, anesthesia, and impaired perception of vibration and pain, but the most vexing clinical problems are the results of autonomic polyneuropathy. Because cardiac innervation is defective, pain and angina are frequently absent when the patient has ischemic heart disease and myocardial infarction. Further consequences of autonomic polyneuropathy are gastroparesis, that is, delayed emptying of gastric contents into the gut, and diarrhea or constipation (often alternating with each other). These problems are caused by impaired intestinal innervation,

Figure 29.11 Proportion of type 2 diabetic patients with progression of nephropathy according to categories of blood pressure. Progression risk according to categories of night:day diastolic BP (median value <85% or ≥85%), and 24 hour ambulatory pulse pressure (PP) (median value <57.5% or ≥57.5%). (From reference 51.)

often complicated by intestinal bacterial overgrowth because of stasis. Finally, urogenital abnormalities, such as erectile impotence or detrusor paresis with delayed and incomplete emptying of the bladder, are frequent.

The major macrovascular complications are stroke, coronary heart disease, and peripheral vascular disease.⁵² These complications are up to five times more frequent in diabetic patients with than without DN.

Survival in Patients with Diabetic Nephropathy

The presence of DN greatly increases mortality in both type 1 and type 2 diabetes. Compared with the background population, mortality in patients with type 1 diabetes and no proteinuria is elevated only twofold to threefold; in contrast, it is increased 20- to 200-fold in patients with proteinuria.⁵³

The major increase in risk starts when microalbuminuria has developed (Fig. 29.13). An increased risk is found even in the upper normal range of albuminuria (Fig. 29.14). Urinary albumin excretion is a good predictor of CV events during the first 5 years after measurement, but repeating the measurement several years later also detects progression, which is also associated with increased CV risk.⁵⁴ It is widely thought that the presence of albuminuria reflects generalized endothelial cell dysfunction, thus increasing the risk of atherosclerosis. Its presence is also associated with many CV risk factors, such as elevated BP, dyslipoproteinemia, increased platelet aggregation, increased C-reactive protein concentration, and others. An added risk

Figure 29.12 Association between manifestations of the diabetic foot syndrome (DFS) in type 1 and 2 diabetes patients classified according to chronic kidney disease (CKD) stages. Only patients with albuminuria were studied. All patients in a CKD stage were considered 100%. DFS increases with higher CKD stages. (From reference 55.)

factor is presumably the association with autonomic polyneuropathy, the presence of which predicts death from myocardial infarction or arrhythmia (sudden death).

RENAL PATHOLOGY

After the onset of diabetes, kidney weight increases by an average of 15%. Renal size remains increased until overt nephropathy is established. In most patients with type 1 diabetes, there is a sustained increase in glomerular volume and glomerular capillary luminal volume. Although atrophic ischemic glomeruli are present, some of the nonfunctioning glomeruli fill up with material staining with periodic acid–Schiff (PAS), thus preserving their increased dimensions. These changes are accompanied by hypertrophy of the interstitium.

In patients with a duration of diabetes of more than 10 years irrespective of whether nephropathy is present, GBM thickening up to three times the normal range of 270 to 359 nm is an almost universal feature (Fig. 29.15). In advancing DN,

there is a consistent correlation between GBM thickness and fractional mesangial volumes with the urinary albumin excretion rate.

Nodular glomerular intercapillary lesions in advanced DN were described in 1936 by Kimmelstiel and Wilson (Fig. 29.16C). The nodules are located in the central regions of peripheral glomerular lobules as well-demarcated eosinophilic and PAS-positive masses (Fig. 29.16C and D). When they are not acellular, they contain pyknotic nuclei. It is suggested that they result from microaneurysmal dilation of the associated capillary followed by mesangiolysis and laminar organization of the mesangial debris with lysis of the center of the lobule. Foam cells often surround the nodules. These appearances are pathognomonic for diabetes but are reported in only 10% to 50% of biopsy specimens in both type 1 and type 2 diabetes. Nodules are also seen in membranoproliferative glomerulonephritis (MPGN) (see Chapter 21), in amyloidosis and light-chain deposition disease (LCDD) (see Chapter 26), and very rarely without diabetes (see Chapter 27); specific stains and immunofluorescence (IF)

findings, respectively, will clarify the diagnosis. When there are no nodules seen, specific staining should be used to exclude amyloid.

The diffuse glomerular lesion is more frequent than the nodular lesion, with an incidence of more than 90% for patients with type 1 diabetes longer than 10 years in duration and an incidence of 25% to 50% in patients with type 2 diabetes.⁵⁶ It comprises an increase of mesangial matrix extending to involve the capillary loops (see Fig. 29.16B). In contrast to nodular lesions, which are of little functional significance, the degree of diffuse glomerulosclerosis correlates with the clinical manifestations of worsening renal function. Accumulation of mesangial matrix is the feature most consistently associated with progression.⁵⁷ In more severe disease, the capillary wall thickening and mesangial expansion lead to capillary narrowing (Fig. 29.15B) and hyalinization, with accompanying periglomerular fibrosis.

Podocytes are involved early in the course of DN in type 1 and type 2 diabetes mellitus (Fig. 29.17), and an increase in foot

Figure 29.13 Impact of microalbuminuria and macroalbuminuria on mortality. The impact of microalbuminuria and macroalbuminuria on mortality was evaluated prospectively in 328 Caucasian patients with non-insulin-dependent diabetes mellitus (DM) observed for 5 years. Microalbuminuria and macroalbuminuria led to a significant increase in total mortality compared with patients who remained normoalbuminuric. (From reference 53.)

Figure 29.14 Event-free survival for cardiovascular (CV) morbidity and mortality after follow-up screening in the PREVENT study. Individuals are stratified according to the presence of a high or low urinary albumin excretion (UAE). High and low UAE are defined by either the UAE measurement from the baseline screening (orange and violet lines) of approximately 4.2 years before follow-up screening or the repeated UAE measurement at time of the follow-up screening (blue and green lines). To allow comparison, the survival curves for the 6800 individuals with either the baseline or follow-up measurement of UAE are plotted in the same graph. A high UAE (dashed lines) is defined as a UAE ≥ 16.2 mg/24 h, being the 75th percentile of UAE with use of the UAE measurement of the baseline screening. (From reference 54.)

Figure 29.15 Electron microscopy of structural changes in diabetic nephropathy (DN). A, Glomerular basement membranes (GBMs) are diffusely thickened. B, The expanded mesangium encroaches on the capillary spaces (arrows).

Figure 29.16 Light microscopy of structural changes in diabetic nephropathy (DN). **A**, Normal glomerulus (periodic acid-Schiff). **B**, Diffuse glomerular lesion: widespread mesangial expansion (periodic acid-Schiff). **C**, Nodular lesion as well as mesangial expansion; there is a typical Kimmelstiel-Wilson nodule at the top of the glomerulus (arrow) (periodic acid-Schiff). **D**, Nodular lesion: methenamine silver staining showing the marked nodular expansion of mesangial matrix.

Figure 29.17 Electron micrograph of the external surface of glomerular tufts from rats after removal of Bowman's capsule by freeze-fracture. *Left*, A normal rat kidney with podocyte cell body; the primary processes and terminal foot processes resting on the glomerular capillary basement membrane are clearly seen. *Right*, The decrease in the density of foot processes and the denuded glomerular capillary basement membrane are apparent. (From reference 59)

process width is already observed in microalbuminuric type 1 diabetics.⁵⁸ Longitudinal studies in DN demonstrated a reduction in podocyte number that closely correlated with proteinuria. Renal biopsy specimens from Pima Indians with type 2 diabetes showed a broadening in podocyte foot processes and a concomitant reduction in the number of podocytes per glomerulus.⁶⁰

Arteriolar lesions are prominent in diabetes. Hyaline material progressively replaces the entire wall structure and involves both the afferent and efferent vessels, which is highly specific for diabetes.

The tubules and the interstitium may show a variety of changes, including tubular cell vacuolization and tubulointerstitial fibrosis.⁶¹ In patients with glycemia above 500 mg/dl and severe glycosuria, Armani-Ebstein lesions can be found (Fig.

29.18). They consist of deposits of glycogen in the tubular epithelial cells (pars straight of proximal convoluted tubule and loop of Henle) but are very rarely seen today. Tubulointerstitial leukocyte infiltration is often found in DN. Tubulointerstitial fibrosis and tubular atrophy are presumably the best pathologic correlates for the progressive decline in GFR. Tubulointerstitial fibrosis and renal arteriosclerosis are more prevalent in type 2 than in type 1 diabetics. Renal structure is, in fact, heterogeneous in type 2 diabetic patients; only a subset has typical diabetic glomerulopathy, whereas a substantial proportion has more advanced tubulointerstitial and vascular rather than glomerular lesions or has normal or nearly normal renal structure.⁶² In a proportion of patients with type 2 diabetes, the kidney has an appearance that is more suggestive of glomerular ischemia or tubulointerstitial disease.

DIAGNOSIS

The diagnosis of DN is based on the detection of proteinuria. In addition, most patients also have hypertension and retinopathy. The main diagnostic procedures in the patient with suspected DN include:

- Measurement of urinary albumin or protein
- Measurement of serum creatinine concentration and estimation of GFR
- Measurement of BP
- Ophthalmologic examination.

Measurement of Albuminuria or Proteinuria

Microalbuminuria is arbitrarily defined as the excretion of 30 to 300 mg/24 h albumin in at least two of three consecutive

nonketotic sterile urine samples (Fig. 29.19). There is substantial intraindividual day-to-day variation of albumin excretion (coefficient of variation, 30% to 50%) and also between day and night collections (Fig. 29.20). Even in the upper quantiles of so-called normoalbuminuria, however, the risk of progression and of CV events is definitely elevated. In this range of albumin concentrations, albumin is normally not detected by nonspecific tests for protein (e.g., Biuret reaction). Albumin can be detected, however, by use of specific techniques such as dipstick, enzyme-linked immunosorbent assay, nephelometry, and radioimmunoassay. Instead of difficult to obtain 24-hour urine collections, the albumin concentration can be determined in spot urine or, better, first-void morning urine samples. The normal range is 20 to 200 µg/min or 20 to 200 µg/ml.

The detection of urinary albumin is a specific indicator of DN only if confounding factors such as fever, physical exercise, urinary tract infection (UTI), nondiabetic renal disease, hematuria from other causes, heart failure, uncontrolled hypertension, and uncontrolled hyperglycemia have been excluded.

Figure 29.18 Armani-Ebstein lesions of tubular cells (arrows) that occur during very high hyperglycemia and massive glucosuria. These lesions consist of deposits of glycogen and are rarely seen today.

Urinary Albumin Excretion Rate		
Condition	UAER	
	24 hr (mg/day)	Overnight (µg/min)
Normoalbuminuria	>30	>20
Microalbuminuria	30–300	20–200
Overt nephropathy	>300	>200

Figure 29.19 Urinary albumin excretion rate (UAER). Levels of 24 hour and overnight UAE are diagnostic for microalbuminuria and overt diabetic nephropathy (DN).

Figure 29.20 Circadian variation of urinary albumin excretion (UAE). UAE is lower in resting conditions at night than during daytime activity. Relationship between UAE assessed on two different days 1 week apart in patients with type 1 diabetes (open circles) and primary hypertension (closed circles). There is substantial intraindividual day-to-day variation of albumin excretion and also between day and night collections. (From reference 63.)

The main advantage of searching for microalbuminuria early in the course of diabetes is that it predicts a high renal and CV risk and thus allows targeted intervention. The American Diabetes Association (www.diabetes.org) and other societies recommend annual screening of all diabetic patients.

By definition, clinically overt DN (macroalbuminuria) is present if the rate of albumin excretion exceeds 300 mg/day. At this point, usually serum proteins other than albumin are excreted in the urine as well (nonselective proteinuria).

Measurement of Blood Pressure

In measuring the BP in a diabetic patient, one should be aware of several problems:

- In overweight patients with type 2 diabetes, the size of the cuff has to be adapted to the upper arm circumference. When this exceeds 32 cm, cuffs of 18-cm width are indicated.
- Patients with severe autonomic polyneuropathy tend to develop orthostatic hypotension, namely, a decrease of systolic BP by more than 20 mm Hg in the upright position. It is therefore advisable to measure BP in the upright position at regular intervals.
- The circadian BP profile tends to be abnormal in early stages, and even a paradoxical increase in the nighttime BP is not rare. In the diabetic patient with nephropathy, it has been shown that a nighttime increase in BP is independently associated with a 20-fold higher mortality and a higher risk of renal failure. Occasional measurements of ambulatory BP are particularly useful to assess the efficacy of antihypertensive treatment.
- In diabetic patients with sclerosis or calcification of the radial and brachial arteries, pseudohypertension may occasionally occur, that is, spuriously elevated BP values despite normotension by intra-arterial BP measurements. Suspicion of this condition should be raised if a discrepancy is found between modest target organ damage, for example, left ventricular hypertrophy, and very high measured

BP values. Such patients tend to develop marked hypotension even with relatively modest antihypertensive medication.

Measurement of Serum Creatinine and Estimation of Glomerular Filtration Rate

In clinical practice, the serum creatinine concentration is most frequently used to assess renal function, but it may be grossly misleading in wasted patients when muscle mass is low. This problem is particularly frequent in elderly female patients with type 2 diabetes. Therefore, the Kidney Disease Outcome Quality Initiative (KDOQI) guidelines recommend that the GFR be estimated according to the Modification of Diet in Renal Disease (MDRD) study equation (see Chapter 3).

Differential Diagnoses

Although hematuria has been considered one of the atypical features indicating the presence of nondiabetic renal disease among patients with diabetes, the clinical significance of hematuria in the overall course of DN suggests that hematuria could be a sign of DN. Moreover, a study identified hematuric patients with pathologically defined DN, and they all had a significantly lower renal function than nonhematuric patients with DN.⁶⁴ The prevalence of nephrotic syndrome and retinopathy was significantly higher in the cases with hematuric diabetic glomerulosclerosis than in the cases with nonhematuric diabetic glomerulosclerosis.

On the other hand, non-DN is not an uncommon entity in type 2 diabetes. Younger patients with diabetes, shorter duration of diabetes, and the association of proteinuria with the absence of retinopathy strongly suggest renal disease of nondiabetic genesis.⁶⁵ Nondiabetic renal disease is a heterogeneous group. Membranous nephropathy (MN), FSGS, acute interstitial nephritis, postinfectious GN, and IgA nephropathy have been described in type 2 diabetic patients in whom DN was suspected on clinical grounds (Fig. 29.21).

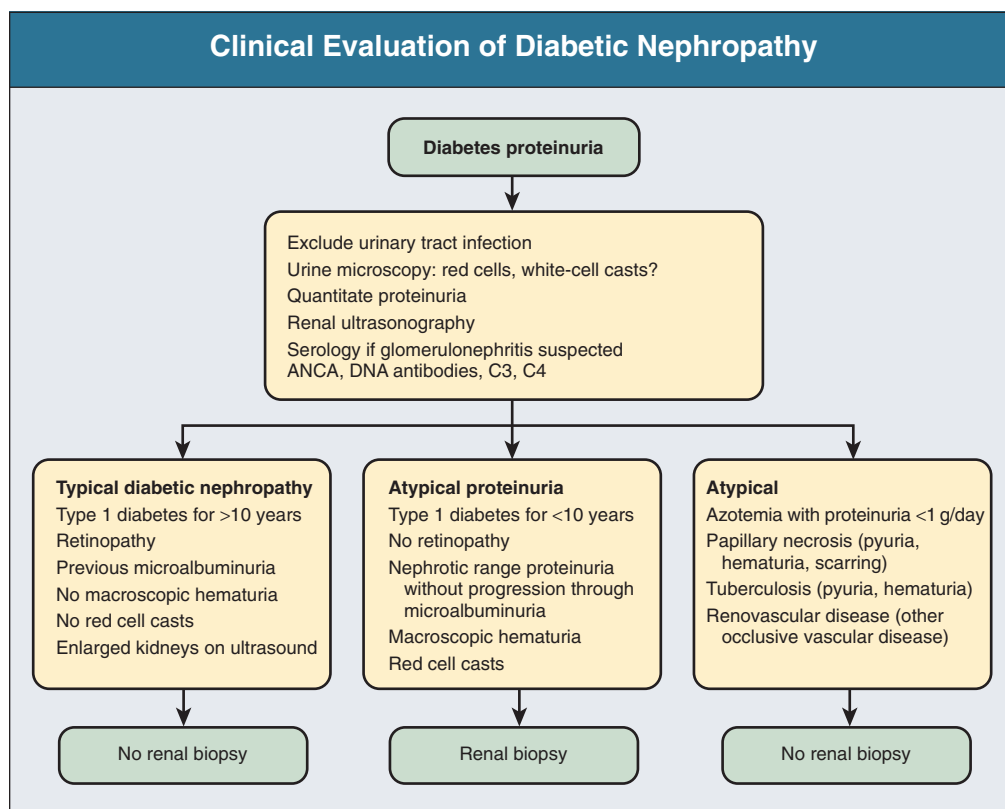

Figure 29.21 Pathologic diagnoses other than diabetic nephropathy are found in more than half of patients with type 2 diabetes with proteinuria. A total of 233 patients were studied; 53.2% (124 patients) had a diagnosis of nondiabetic renal diseases. FSGS, focal segmental glomerulosclerosis; IgAN, IgA nephropathy; MCD, minimal change disease; Mes, mesangial immune complex glomerulonephritis; MGN, membranous nephropathy; Pauci, ANCA-positive pauci-immune glomerulonephritis; SLE, systemic lupus erythematosus. (From reference 65.)

Figure 29.22 Clinical evaluation of diabetic renal disease. ANCA, antineutrophil cytoplasmic antibody.

Indications for Renal Biopsy

Further investigation including a renal biopsy should be considered (Fig. 29.22):

- If retinopathy is not present in type 1 diabetes with proteinuria or moderately impaired renal function (absence of retinopathy does not exclude DN in type 2 diabetes).
- If the onset of proteinuria has been sudden and rapid, particularly in type 1 diabetes, and if the duration of type 1 diabetes has been less than 5 years or if the evolution has been atypical, for example, without transition through the usual stages, particularly the development of nephrotic syndrome without previous microalbuminuria.
- If macroscopic hematuria is present or an active nephritic urinary sediment is found that is suggestive of GN, such as acanthocytes and red cell casts; the sediment in DN typically is unremarkable apart from some occasional erythrocytes.
- If the decline of renal function is exceptionally rapid or if renal dysfunction is found without significant proteinuria (first, of course, renovascular disease must be excluded Fig. 29.23).

If renal ultrasound reveals small kidneys or a size difference, it is prudent not to perform biopsy. Overall, renal biopsy is indicated only in a small minority of diabetic patients.

Points to Consider in Dealing with a Diabetic Patient with Impaired Renal Function

When seeing a diabetic patient with CKD, one should:

- Assess the cause of CKD (acute versus chronic renal impairment; DN versus alternative causes of renal damage).

Figure 29.23 Glomerulonephritis (GN) superimposed on diabetic nephropathy (DN). A glomerulus showing a cellular crescent with rupture of Bowman's capsule superimposed on nodular DN. The patient, known to have DN, presented with rapidly deteriorating renal function and red cell casts in the urine.

- Assess the magnitude of proteinuria and the rate of progression.
- Search for evidence of the typical extrarenal microvascular and macrovascular complications of diabetes.

The majority of diabetic patients with heavy proteinuria or renal failure suffer from DN. Renal ischemia (atherosclerotic renal artery stenosis or cholesterol embolism) is common in diabetics, and a substantial proportion of type 2 diabetic patients have small kidneys and low GFR without albuminuria, possibly as the result of macrovascular disease.

If UTIs occur, they are more severe in the diabetic compared with the nondiabetic patient. Purulent papillary necrosis and intrarenal abscess formation, however, have become rare nowadays.

Diabetic patients with nephropathy are particularly prone to development of AKI after administration of nonsteroidal anti-inflammatory drugs (NSAIDs) or radiocontrast media or after CV events or septicemia. Preventive measures are discussed in Chapter 69. AKI superimposed on preexisting DN carries a very poor prognosis.

Prevention and Treatment of Diabetic Nephropathy

Li-Li Tong, Sharon Adler

Nephropathy in patients with diabetes, primarily type 2, remains the leading cause of end-stage renal disease (ESRD) in the Western world. Examination of trends in ESRD attributed to diabetic nephropathy (DN) in the United States suggests a possible plateau in incidence in recent years.¹ The implementation of renoprotective therapy in the past 2 decades may have contributed to this phenomenon.

Classically, DN evolves through several clinical stages based on the values of urine albumin excretion (UAE): normoalbuminuria, microalbuminuria, and macroalbuminuria or overt nephropathy. The level of UAE has predictive importance for both renal outcome and cardiovascular (CV) morbidity and mortality and affects the choice of therapeutic intervention. Although difficult, normoalbuminuria is the ideal treatment goal. Understanding of the pathogenesis of hypertension in DN is important for rational selection of therapeutic agents:

- The important role of sodium retention and hypervolemia explains why dietary sodium restriction and diuretics are so effective.
- The activation of the intrarenal renin-angiotensin-aldosterone system (RAS) explains the efficacy of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs).
- The activation of the sympathetic nervous system and its role in the genesis of renal hypertension presumably explain why β -blockers are effective in retarding progression.

This chapter reviews the current preventive and therapeutic strategies that promote renoprotection and cardioprotection in diabetic patients. A summary of these strategies is shown in [Figure 30.1](#). In general, the treatment principles for established DN are similar to those adopted for the prevention of DN, although multiple and more intensive strategies may be required for treatment. Special considerations are indicated in the management of the diabetic patient with advanced chronic kidney disease (CKD) (see Chapter 31). Many therapeutic issues discussed here are not specific for DN and thus are also relevant for CKD in general (see Chapter 76).

PREVENTION OF DIABETIC NEPHROPATHY

Prevention and early detection of nephropathy improve patient outcome. General measures for prevention of DN include glycemic control and blood pressure control. Because diabetes is associated with increased risk for CV morbidity and mortality, treatment of dyslipidemia as well as diet and lifestyle modifications, including physical activity and weight reduction as

appropriate and smoking cessation, can significantly lower the CV risks.

Glycemic Control

In type 1 diabetic patients, strict glycemic control decreased the risk for microalbuminuria. The Diabetes Control and Complications Trial (DCCT) ([Fig. 30.2](#)) compared the effects of intensive glucose control with conventional treatment on the development and progression of the long-term complications of type 1 diabetes. During a 9-year period, patients receiving intensive therapy (mean HbA_{1c} 7%) had a 35% to 45% lower risk for development of microalbuminuria compared with the control group (mean HbA_{1c} 9%).² Renoprotection can persist even after a return to less intensive therapy.³

For type 2 diabetes, several major studies have demonstrated a lower risk of nephropathy with stricter glycemic control. In a study design similar to the DCCT, the Kumamoto study found a 60% reduction in the rate of microalbuminuria in relatively young nonobese type 2 diabetic patients receiving intensive glycemic treatment (HbA_{1c} 7.1%) compared with conventional treatment (HbA_{1c} 9.4%).⁴ In the U.K. Prospective Diabetes Study (UKPDS) trial, newly diagnosed patients with type 2 diabetes were randomly assigned to intensive management (HbA_{1c} 7.0%) with a sulfonylurea or insulin or to conventional management (HbA_{1c} 7.9%) with diet alone. After 9 years of intensive therapy, relative risk reduction for the development of microalbuminuria was 24%.⁵ After termination of the study, patients were observed for a further 10 years. The differences in HbA_{1c} were lost within 1 year, but a 24% lower risk of microvascular disease and myocardial infarction (–15%) persisted. All-cause mortality (–13%) was also reduced. This suggests glycemic memory (“legacy effect”), that is, long-lasting beneficial effects of good glycemic control explained by long-lasting modification of transcription of genes relevant in the genesis of complications. This observation underlies the importance of early glycemic control before complications have set in.

Three major trials testing whether glycemic control reduced cardiovascular disease (CVD) risk in type 2 diabetics have considerably increased our knowledge of and refined our approach to establishing glycemic goals. The Action in Diabetes and Vascular Disease, Perindopril and Indapamide Controlled Evaluation (ADVANCE) study showed that intensive blood glucose control (HbA_{1c} 6.5% versus 7.3%) yielded a 10% relative reduction in the combined outcome of major macrovascular and microvascular events, primarily as a consequence of a 21%

Management of Type 1 Diabetes	
Stage	Management
Normoalbuminuria/ Normotensive	Optimize glycemic control (target HbA _{1c} <7%)
Normoalbuminuria/ Hypertensive	Consider ACE inhibitor or ARB as antihypertensive agent (target BP <130/80 mm Hg); dietary sodium restriction +/- diuretic therapy
Microalbuminuria/ Normotensive	Start ACE inhibitor or ARB, titrate dose as tolerated to normoalbuminuria
Microalbuminuria/ Hypertensive	Titrate ACE inhibitor or ARB as tolerated; consider addition of selective aldosterone receptor antagonist (e.g., spironolactone, eplerenone), nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil), direct renin inhibitor (e.g., aliskiren); dietary sodium restriction +/- loop or thiazide diuretic; treat to normoalbuminuria and BP <130/80 mm Hg
Overt proteinuria	Continue management as above with aggressive BP control; treat cardiovascular risks and consider aspirin therapy, statin therapy, smoking cessation, weight reduction as appropriate
Declining glomerular filtration rate (GFR)	Provide nutrition counseling regarding sodium, potassium, and phosphorus restriction; avoid protein-calorie malnutrition; treat anemia; prepare for dialysis or transplantation when GFR is <20 ml/min

Figure 30.1 Management of type 1 diabetes. A similar strategy can be used in patients with type 2 diabetes with increased emphasis on management of cardiovascular risk factors. In considering the management of patients with diabetic and chronic kidney disease (CKD), a global perspective is required, which includes therapy that retards progression of kidney disease as well as therapy that minimizes cardiovascular risk and addresses other major diabetic complications, including coronary artery disease, peripheral vascular disease, retinopathy, neuropathy, gastroparesis, and dyslipidemia. ACE, angiotensin-converting enzyme; ARB, angiotensin II receptor blocker; BP, blood pressure.

Figure 30.2 Diabetes Control and Complications Trial. Intensive glucose control was associated with a decreased risk for the subsequent development of microalbuminuria in type 1 diabetes. (Modified from reference 2.)

relative reduction in nephropathy.⁶ However, the Food and Drug Administration recently halted one of the arms of the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial when it became apparent that very tight glycemic control (lowering of HbA_{1c} to a median of 6.4% versus 7.5% with conventional control) was associated with a higher mortality (increase in risk by 22%; $P = .04$).⁷ A third major study of tight glucose control in type 2 diabetics, the Veterans Affairs Diabetes Trial (VADT), found no significant reduction in CV deaths or events during 7.5 years in high-risk patients treated aggressively for glycemic control (median HbA_{1c} 6.9%) compared with standard therapy (median HbA_{1c} 8.4%).⁸

It is apparent that glycemic control in type 2 diabetic patients must be individualized and take into account the patient's duration of diabetes, presence of CVD, and microvascular risks and complications as well as previous glycemic control and susceptibility to and awareness of hypoglycemia. In patients with recently diagnosed diabetes and no prior CVD events, strict glycemic control can reduce the risk of nephropathy and other microvascular complications. In patients with long-standing diabetes and known CVD, data do not support strict glycemic control in reducing the risk of further CVD events or mortality. The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) guideline recommends lowering of HbA_{1c} levels to 7.0% for both type 1 and type 2 diabetic patients.⁹ At even lower glycemic targets, any potential renoprotective effects of tight glucose control must be counterbalanced by the possibility of more frequent hypoglycemic episodes.

Antihypertensive Therapy

Hypertension is present in about 40% of type 1 and 70% of type 2 diabetic patients with normoalbuminuria.¹⁰ Higher blood pressure level is associated with an increased risk for the development of nephropathy; and in patients with established nephropathy, it is associated with more rapid progression and increased risk of kidney failure.¹¹ The National Kidney Foundation, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), and the American Diabetes Association recommend a target blood pressure value of below 130/80 mm Hg in diabetic patients.¹²

Renin-Angiotensin-Aldosterone System Blockade

The role of RAS blockade in normotensive, normoalbuminuric diabetic patients for the primary prevention of DN is controversial. Most patients with diabetes do not develop DN, even after long periods of uncontrolled hyperglycemia, and there are potential risks and side effects with the use of RAS blocking drugs, including their potential teratogenicity in pregnancy. In a recent post hoc analysis of three randomized controlled trials conducted as part of the multicenter Diabetic Retinopathy Candesartan Trials (DIRECT) program, which included normotensive and normoalbuminuric type 1 diabetics and normoalbuminuric type 2 diabetics with or without hypertension, the ARB candesartan was found to have no effect on the development of microalbuminuria.¹³

In hypertensive diabetic patients, an ACE inhibitor or an ARB is effective as a first-line antihypertensive agent. The Bergamo Nephrologic Diabetes Complications Trial (BENEDICT), which randomized hypertensive normoalbuminuric type 2 diabetic patients to placebo, verapamil, trandolapril, or a

combination of verapamil plus trandolapril, showed less progression to microalbuminuria in patients receiving trandolapril either alone or in combination with verapamil.¹⁴ Verapamil alone was not different from placebo. There were similar findings in smaller studies with other RAS inhibitors, implicating a class effect.¹⁵ Very long term studies would be required to demonstrate the effects of RAS blockade on the clinically important outcomes of death, dialysis, and doubling of serum creatinine level in normoalbuminuric patients. It is likely that therapy for the prevention of DN will be guided exclusively by studies using albuminuria as a surrogate.

Treatment of Dyslipidemia

There are few clinical data concerning the effects of lipid lowering alone in preventing DN. In the Diabetes Atherosclerosis Intervention Study (DAIS), type 2 diabetic patients taking fenofibrate had a significantly lower rate of progression from normoalbuminuria to microalbuminuria at 3 years compared with placebo.¹⁶ Current guidelines recommend a goal for low-density lipoprotein (LDL) cholesterol of below 100 mg/dl (2.57 mmol/l) for diabetic patients in general and below 70 mg/dl (1.81 mmol/l) for diabetic patients with CVD.¹⁷

Nonpharmacologic Interventions

For all diabetics, emphasis should be placed on lifestyle modification to lower the risk of CV events, including dietary restriction of salt and saturated fat, weight reduction and exercise as appropriate, and smoking cessation. Smoking in particular is an independent risk factor for the development of nephropathy in type 2 diabetes and is associated with an accelerated loss of renal function.¹⁸

TREATMENT OF DIABETICS WITH MICROALBUMINURIA OR OVERT NEPHROPATHY

For diabetic patients with incipient or established DN, the optimal therapeutic approach to reduce the rate of progression of nephropathy and to minimize the risk for CV events involves aggressive management of hypertension with emphasis on a RAS blocker combined with management of dyslipidemia, hyperglycemia, and albuminuria as well as diet modification, exercise, and smoking cessation. Such multifactorial therapy in the Steno type 2 trial in type 2 diabetics included management of hyperglycemia and of hypertension, ACE inhibition, statins, aspirin, reduction of fat intake, light to moderate exercise, and cessation of smoking.^{19,20} Impressive lowering of the risk of CV disease, nephropathy, retinopathy, and autonomic polyneuropathy was noted after 7.7 years, and even a delayed reduction of mortality was seen.

In general, patients with DN require multiple antihypertensive agents (including RAS blocking agents) to achieve blood pressure goal, intensive insulin therapy in type 1 diabetes, two or more drugs for glucose control in type 2 diabetes, at least one lipid-lowering agent, and an aspirin or other antiplatelet agent for CV protection. One obstacle to achieving adherence is the number of medicines and the complexity of these regimens. Therefore, treatment of patients with DN needs to be individualized and requires considerations of the cost, side effects, and convenience of the drug regimen. Regular monitoring of UAE and serum creatinine concentration to assess response to therapy and progression of disease is required.

Figure 30.3 Control of blood pressure reduces the risk for progression in type 1 diabetic nephropathy. (Modified from reference 21.)

Antihypertensive Therapies

In type 1 and type 2 diabetic patients with established DN, hypertension is an almost universal finding and is associated with volume expansion and salt sensitivity. The absence of hypertension in an untreated patient with overt nephropathy should raise suspicion for underlying cardiac problems. Uncontrolled hypertension is associated with more rapid progression of DN¹¹ and increased risk of fatal and nonfatal CV events.²² Thus, effective treatment of systemic hypertension is arguably the single most important strategy in the treatment of established DN (Fig. 30.3). Some have suggested that the overall effect of lowering blood pressure may be more important than the type of antihypertensive agent used.²³ Antihypertensive therapies, irrespective of the agent used, reduce UAE, delay progression of nephropathy, postpone renal insufficiency, and improve survival in both type 1 and type 2 diabetics with DN.²⁴

The current recommended blood pressure target for all diabetics is below 130/80 mm Hg, but even lower systolic pressures may be more beneficial in diabetic patients with established nephropathy. In a secondary analysis of the Irbesartan Diabetic Nephropathy Trial (IDNT), progressive lowering of systolic blood pressure to 120 mm Hg was associated with improved renal and patient survival, an effect independent of baseline renal function.²⁵ However, mortality increased with systolic blood pressure below 120 mm Hg, although a cause and effect relationship cannot be inferred from the data. The optimal lower limit for systolic blood pressure, therefore, remains unclear. From a safety perspective, diastolic pressure is also important. Low diastolic pressures are poorly tolerated, and the incidence of myocardial infarction and mortality increases at values below 70 mm Hg, at least in patients with coronary heart disease, presumably because coronary perfusion occurs only during diastole. Indeed, in the IDNT study, CV mortality increased not only with higher systolic pressures but also with low diastolic pressure.

Renin-Angiotensin-Aldosterone System Blockade in Diabetic Nephropathy

In diabetic patients with established DN, RAS blockade with ACE inhibitors or ARBs confers renoprotection that is

independent of blood pressure reduction. Intraglomerular hemodynamic and nonhemodynamic renal effects of angiotensin II, some of which are probably mediated by the fibrotic agent transforming growth factor β , best explain the observed renoprotection. In support of this hypothesis is a large body of evidence in *in vitro* models of DN showing cellular effects of RAS inhibition that are consistent with benefit independent of blood pressure effects (see Chapter 29).

Although many studies have demonstrated a beneficial effect of ACE inhibitors and ARBs in retarding progressive renal disease, they did not differentiate between the relative contributions of the RAS blockade versus aldosterone system blockade. In fact, plasma aldosterone levels are elevated in a subset of patients despite ACE inhibitor and ARB therapy (also known as aldosterone escape or aldosterone breakthrough). In studies that defined aldosterone escape as any increase from an individual's baseline serum aldosterone level (i.e., before ACE inhibitor or ARB therapy), the incidence ranged from 40% during 10 months to 53% during 12 months.²⁶ In addition to its classic effects of promoting sodium retention and enhancing potassium and magnesium excretion, aldosterone promotes tissue inflammation and fibrosis.²⁷ Small studies have demonstrated considerably faster decline in glomerular filtration rate (GFR) in patients who experienced aldosterone escape (median, 5.0 ml/min per year) than in those who did not (median, 2.4 ml/min per year). Aldosterone blockade, independent of RAS blockade, reduces proteinuria and retards progression of nephropathy. Current evidence is not strong enough to support widespread screening for aldosterone escape. However, in selected patients, additional aldosterone blockade may represent optimal therapy for patients who show aldosterone escape during treatment with an ACE inhibitor or an ARB and who no longer show maximal antiproteinuric effects with these agents.

RAS Blockade in Type 1 Diabetics

In type 1 diabetics with microalbuminuria, ACE inhibitors reduce the risk of progression to overt nephropathy.^{28,29} In a meta-analysis of 12 placebo-controlled trials in 698 normotensive patients with type 1 diabetes and microalbuminuria treated with ACE inhibitors, the majority for more than 2 years, treatment was associated with a 60% reduction in progression to macroalbuminuria and a threefold increase in regression to normoalbuminuria.³⁰ Changes in blood pressure cannot entirely explain the antiproteinuric effect of ACE inhibitors.

In patients with macroalbuminuria or overt nephropathy, the Collaborative Study Group trial demonstrated that captopril reduced albuminuria, slowed the decrement in GFR, and delayed the onset of kidney failure compared with placebo.³¹ The beneficial effect of captopril was greater in patients with reduced GFR at baseline largely because the end point, a doubling of baseline serum creatinine level, is achieved more quickly in these patients.

There are insufficient data and no large long-term clinical trials to demonstrate the efficacy of ARBs in type 1 DN. Nevertheless, based on the shared properties of ACE inhibitors and ARBs in inhibiting the RAS, there is reason to believe that both are effective in the treatment of type 1 DN.

RAS Blockade in Type 2 Diabetics

In type 2 diabetics, there are more data available on the renoprotective effect of ARBs compared with ACE inhibitors. In the stage of microalbuminuria, the IRMA 2 study showed that the ARB irbesartan reduces progression to overt nephropathy by 70% in hypertensive type 2 diabetic patients during a 2-year

follow-up period.³² In the MARVAL trial, the ARB valsartan (80 mg/day) produced a greater reduction in UAE than did amlodipine (44% versus 8%) with the same degree of blood pressure reduction, suggesting that the antiproteinuric effect of ARBs is blood pressure independent.³³

In type 2 diabetic patients with macroalbuminuria and decreased GFR, large randomized controlled trials (IDNT and RENAAL) have demonstrated that ARBs are effective in lowering proteinuria and decreased the relative risk of reaching the composite end point of death, dialysis, and doubling of serum creatinine level.^{34,35} However, the risk reduction for reaching the composite end point was only 18% to 20% in these studies in patients with type 2 diabetes and nephropathy, compared with the more robust risk reduction of ~50% in patients with type 1 diabetes receiving captopril. ARBs did not decrease CV death in these trials but did decrease the incidence of heart failure.

Compared with ARBs, data on the efficacy of ACE inhibitors in type 2 DN are less strong, largely because the studies were underpowered by small sample size or short follow-up. Nevertheless, some studies did show that ACE inhibitor use results in greater reduction in albuminuria and slower decrease in GFR compared with other antihypertensive agents. Whereas both ACE inhibitors and ARBs are probably effective for treatment of DN in patients with type 2 diabetes, few studies have directly compared their efficacy. In a small randomized controlled trial of type 2 diabetes and early nephropathy with 5 years of follow-up, the ARB telmisartan was not inferior to the ACE inhibitor enalapril in providing long-term renoprotection.³⁶ Some pharmaceutical companies marketing both ACE inhibitors and ARBs have attempted to make the argument that particular characteristics of individual agents within these classes, such as differences in tissue levels or differential effects on the metabolic syndrome, confer some with special beneficial properties. To date, there have not been high-quality prospective randomized trials proving such superiority for any particular agent for DN.

Combination Therapy of RAS Antagonists in Diabetic Nephropathy

ACE inhibitors and ARBs have been used simultaneously for therapeutic synergy in patients with nondiabetic renal disease (COOPERATE trial),³⁷ but doubts about the data have led to a formal retraction of the paper.³⁸ In both type 1 and type 2 diabetics with nephropathy, results of several earlier small trials suggested that the combination of an ACE inhibitor and an ARB is more effective in reducing blood pressure and proteinuria than is either drug alone.^{39,40} However, there were no data from these trials on the effect of combined therapy on kidney disease progression. The recent ONTARGET study, which included diabetic and nondiabetic patients with CV risk, failed to show improved CV outcomes from a combination of an ACE inhibitor and an ARB. Instead, it showed increased renal functional decline, a trend toward an increase in the development of ESRD that fell just short of statistical significance, and a possible increase in mortality.⁴¹ Whereas most of the ONTARGET study population did not have overt DN, the data nevertheless suggest caution in the use of these agents in combination, which is presumably not superior to dose escalation of the monotherapies. ACE inhibitors and ARBs have also been studied in combination with aldosterone receptor antagonists (e.g., spironolactone, eplerenone)⁴² and a direct renin inhibitor (aliskiren)⁴³; further reductions in proteinuria have been reported with these combinations compared with the ACE inhibitor or ARB alone. However, no studies with these combinations have yet been

reported in which the primary end point has been death, dialysis, or doubled serum creatinine level.

Dosing and Adverse Effects Associated with ACE Inhibitors and ARBs

The antiproteinuric effect of ACE inhibitors and ARBs is at least in part independent of blood pressure reduction, and in individual patients, proteinuria may continue to respond to dose escalations beyond those recommended for blood pressure control.⁴⁴ Unfortunately, maximal dosing of ACE inhibitors or ARBs may be limited by side effects, including hyperkalemia, hypotension, and reduced GFR. In women of reproductive age, counseling about pregnancy prevention and contraceptive use should begin before an ACE inhibitor or an ARB is started.

An increase in serum creatinine concentration of up to 30% may occur in proteinuric patients with renal impairment after an ACE inhibitor is started. This rise in creatinine is associated with long-term renoprotection, and therefore the ACE inhibitor should not necessarily be stopped in these patients.⁴⁵ Increases in serum creatinine concentration above 30% after initiation of an ACE inhibitor should raise the suspicion of renal artery stenosis. Aggressive dose increments of ACE inhibitors or ARBs, especially in conjunction with diuresis, can precipitate acute kidney injury. In advanced CKD, although ACE inhibitors and ARBs are not contraindicated, the introduction of these agents or injudicious dose increments may precipitate the need for dialysis prematurely, so some caution is appropriate.

Other Antihypertensive Agents in Diabetic Nephropathy

Diuretics

The antiproteinuric effects of RAS blockade are enhanced by sodium restriction. Thus, patients receiving ACE inhibitors or ARBs should be instructed to take a low-sodium diet (e.g., less than 2 g of sodium per day). The combination of a loop diuretic or a thiazide diuretic with agents that block the RAS may be more effective than either type of treatment alone for lowering blood pressure. Selective aldosterone receptor antagonists (e.g., spironolactone, eplerenone) also reduce proteinuria when they are used alone and have an additive effect on proteinuria when they are used in combination with an ACE inhibitor or ARB.⁴² As discussed earlier, aldosterone blockade may be especially beneficial in patients demonstrating aldosterone escape. The risk of hyperkalemia, however, frequently limits the use of combined aldosterone receptor antagonists with ACE inhibitors or ARBs, especially in patients with reduced GFR.

Calcium Channel Blockers

Nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil) have been shown in some studies to have antiproteinuric effects.⁴⁶ In type 2 diabetic patients with normoalbuminuria, however, nondihydropyridine calcium channel blockers did not reduce the incidence of microalbuminuria relative to placebo,¹⁴ nor do they enhance the effect of ACE inhibitors in preventing microalbuminuria.

Dihydropyridine calcium channel blockers (e.g., nisoldipine, nifedipine, amlodipine) may be used as additional antihypertensive agents, but they have not been shown to reduce albuminuria or to slow the progression of renal disease.⁴⁷ In the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, the long-acting calcium antagonist nisoldipine was compared with the ACE inhibitor enalapril as first-line antihypertensive therapy in

470 hypertensive type 2 diabetic patients. The incidence of fatal and nonfatal myocardial infarctions was significantly higher among those receiving nisoldipine compared with those receiving enalapril during a 5-year study period.⁴⁸ In a meta-analysis, patients with diabetes treated with dihydropyridine calcium channel blockers had more severe proteinuria and a more rapid decline in renal function than did those treated with other antihypertensive agents.⁴⁹

β -Blockers

Classic β -blockers have adverse metabolic effects and are therefore undesirable in diabetics, but this is no longer true for the modern β -blockers carvedilol and nebivolol. Despite insufficient controlled evidence, β -blockade with these novel blockers appears to be useful because of the extremely high CV risk in diabetic patients with nephropathy.

Direct Renin Inhibitors

Aliskiren is the first orally active direct renin inhibitor approved for treatment of hypertension. In the AVOID trial, the addition of aliskiren produced greater reduction in UAE compared with placebo in type 2 diabetic patients with hypertension and nephropathy receiving the maximum recommended dose of losartan (100 mg daily).⁴³ The major side effects of aliskiren relate to its inhibition of the RAS, including hyperkalemia, hypotension, and reduced GFR. Its effect on long-term renal outcomes remains to be seen.

Glycemic Control

Most of the evidence favoring strict glycemic control comes from studies of patients with normoalbuminuria or early stages of DN. Fewer studies addressed intensive glycemic control in patients with advanced stages of DN, in which it may be difficult to show a benefit because the results are confounded by the effects of concomitant hypertension and CVD. Even so, for type 1 diabetic patients with overt nephropathy, there is evidence to support glycemic control in reducing the risk of worsening albuminuria and renal functional decline.^{50,51} Strict glycemic control may also improve renal histology. Renal biopsy specimens from pancreatic transplant recipients in whom true euglycemia is restored showed stabilized glomerular structure at 5 years of follow-up and improved glomerular and tubular structure at 10 years after transplantation.⁵²

For type 2 diabetics with established DN, strict glycemic control may provide some renoprotection but does not protect against macrovascular complications. In the Kumamoto study, there was a reduction in the rate of conversion from microalbuminuria to macroalbuminuria in type 2 diabetic patients receiving intensive glycemic treatment (HbA_{1c} 7.1% with intensive treatment compared with HbA_{1c} 9.4% with conventional treatment).⁴ The ADVANCE study recently confirmed the predicted reductions in new-onset microalbuminuria and nephropathy in patients with nearly normal glycemic control (HbA_{1c} 6.5% versus 7.3%).⁶ In contrast, studies have failed to show a lower rate of major CV events in patients prescribed strict glycemic control. Furthermore, there was a troubling finding from the ACCORD trial, in which type 2 diabetic patients with either established CVD or additional CV risk factors had increased mortality when given intensive glycemic treatment (lowering of HbA_{1c} to a median of 6.4% versus 7.5% with conventional control).⁷

The most appropriate target for glycated hemoglobin for patients with DN is 7.0%, especially for high-risk patients with

established CVD. Lower individualized targets may be appropriate when the focus is the treatment of microvascular disease such as nephropathy, but the potential renal benefits need to be balanced with the increased rates of adverse events such as hypoglycemia, especially in patients with declining GFR due to decreased clearance of insulin or oral hypoglycemic agents.

The most plausible conclusion is that glucose-lowering treatment must be individualized in type 2 diabetes. It should be more aggressive in young patients with short duration of diabetes, high life expectancy, and low risk of hypoglycemia. A more cautious approach is sensible in the elderly patient who has long-standing diabetes, has preexisting CV problems, gains weight with insulin, and is susceptible to hypoglycemic episodes. Type 2 diabetes is a progressive disease with progressive loss of endogenous insulin secretion so that ultimately insulin will often become necessary. The American Diabetes Association and the European Association for the Study of Diabetes guidelines recommend lifestyle intervention first and suggest the addition of basal insulin (most effective), sulfonylurea (least expensive), or thiazolidinediones (no hypoglycemia) if HbA_{1c} values still exceed 7%.

Treatment of Dyslipidemia

Most patients with DN have dyslipidemia, characterized by low levels of high-density lipoprotein (HDL) cholesterol, high triglyceride (TG) levels, and a shift from larger toward smaller LDL cholesterol.⁵³ Dyslipidemia in diabetic patients may contribute to the development of glomerulosclerosis and progressive renal disease.^{54,55}

In type 2 diabetic patients with non-dialysis dependent DN, treatment with statins provides substantial CV benefit.^{56,57} In contrast, statin therapy in ESRD may come too late to translate into improved CV outcomes (see Chapters 31 and 78).

Current guidelines recommend a goal for LDL cholesterol of below 100 mg/dl (2.57 mmol/l) for diabetic patients in general and below 70 mg/dl (1.81 mmol/l) for diabetic patients with CVD.¹⁷ However, LDL cholesterol is not the sole lipid that defines CV risk. As major statin trials have demonstrated, lowering of LDL cholesterol does not prevent the majority of adverse CV events and does not bring the CV risk in diabetics down to the level of nondiabetic patients. This has been referred to as residual CV risk. Atherogenic dyslipidemia, specifically elevated TG, low HDL cholesterol, elevated apolipoprotein β , and elevated apolipoprotein C-III, are thought to be key factors associated with residual CV risk in diabetic patients.⁵⁸ In the UKPDS, elevated TG was independently associated with albuminuria in type 2 diabetic patients. Thus, interventions aimed at improving all lipid targets are required. However, the lack of clinical trial data on the use of combined lipid-altering treatment presents a therapeutic dilemma because it is not known whether this is best achieved by intensification of statin therapy or by supplementation of statin therapy with a fibrate, niacin, or omega-3 fatty acid.

Nonpharmacologic Interventions

Dietary protein restriction may alleviate uremic symptoms in patients at or approaching ESRD. However, it is of uncertain benefit in the treatment of DN. Small trials have shown low-protein diet (0.8 g/kg per day) to significantly reduce proteinuria with an increase in plasma albumin in macroalbuminuric type 2 diabetic patients.⁵⁹ A recent meta-analysis, however, concluded that although low-protein diet improved proteinuria, it is also associated with lower serum albumin concentrations and was not

associated with a significant improvement of renal function in patients with either type 1 or type 2 DN.⁶⁰ Nutritionist counseling is advised for all patients with advanced CKD to avoid protein-calorie malnutrition before renal replacement therapy, which has been shown to be a strong predictor for subsequent increased morbidity and mortality during maintenance dialysis. Furthermore, all patients with DN should be given counseling on salt, potassium, and phosphate restriction as well as choice of carbohydrates and fats.

Lifestyle modifications such as smoking cessation and weight reduction can provide additive renal benefits and lower the risk of CV events in patients with established DN. There is evidence that smoking cessation ameliorates progression of microalbuminuria to macroalbuminuria and improves renal prognosis.⁶¹ Weight reduction may also improve renal outcome. In a small randomized trial of obese (body mass index >27 kg/m²) diabetic and nondiabetic patients with proteinuric renal disease, patients who lost weight through dieting had marked improvement in proteinuria compared with those who lost no weight.⁶²

NEWER TREATMENTS OF DIABETIC NEPHROPATHY

Peroxisome proliferator-activated receptors (PPAR) are ligand-activated transcription factors involved in regulating adipogenesis, insulin sensitivity, inflammation, and blood pressure; they may have a role in the development of nephropathy in type 2 diabetics. Thiazolidinediones (e.g., pioglitazone, rosiglitazone) are PPAR γ agonists with insulin-sensitizing actions. Pioglitazone in combination with the ARB losartan seems to offer greater renoprotection than does losartan alone in short-term studies.⁶³ Currently, it is premature to suggest routine therapy with a thiazolidinedione in DN. The glycosaminoglycan sulodexide has recently been shown to have no benefit for microalbuminuric or overtly proteinuric DN. Serum uric acid is predictive of the development and progression of DN in type 1 diabetic subjects, and experimental lowering of uric acid is protective in experimental DN. These observations suggest that future studies examining the effect of lowering uric acid as a potential therapy are needed. Several other agents, including avosentan (an endothelin A receptor blocker), protein kinase C inhibitors, fenofibrate, pirfenidone, monoclonal anti-connective tissue growth factor antibody, mycophenolate mofetil (MMF), and fish oil, have been evaluated for proteinuric renal disease including DN. There are insufficient data on any of these agents at this time for their use to be advocated in the prevention or treatment of DN. New insights into the molecular mechanisms that underlie the origin and progression of DN are emerging from large-scale genetic and molecular studies in experimental models and humans. It is anticipated that strategies for the prevention and treatment of DN will continue to improve as newer agents become available.

Management of the Diabetic Patient with Chronic Kidney Disease

Dace Trence, Wolfgang Pommer

Diabetic patients with chronic kidney disease (CKD) are the fastest growing population in renal care and dialysis (Fig. 31.1). Many of these patients present to nephrologists with advanced stages of CKD. Renal disease in these subjects may not be due solely to diabetic nephropathy (DN) but may be secondary to hypertensive or vascular disease and in some cases glomerular or tubulointerstitial diseases unrelated to diabetes mellitus (DM). Thus, the initial approach is to identify, if possible, the etiology of the underlying kidney disease to guide specific treatment (see Chapter 29).

The main focus of therapeutic intervention in stage 3 to stage 5 CKD is:

- Prevention of or retarding further progression of CKD.
- Timely treatment of secondary complications of CKD (i.e., Hypertension, acid-base and electrolyte disturbances, anemia, hyperparathyroidism).
- Improvement of the patient's survival by aggressive therapy of coexisting disease, in particular cardiovascular disease (CVD).
- Timely institution of and correct choice of renal replacement therapy (RRT).

Prevention of cardiac death in CKD and retarding progression to end-stage renal disease (ESRD) are the most pressing long-term issues in the diabetic patient with renal disease. Diabetic patients with CKD benefit from a multidisciplinary therapeutic approach involving general practitioners, nephrologists, diabetologists, interventional cardiologists, podiatrists, dietitians, and special renal and diabetes nurse specialists.¹ Although the value of such a multifactorial approach in diabetics with CKD is generally accepted,² it is controversial when to refer to the nephrologist. This is in part constrained by availability of nephrologists and socioeconomic conditions of different health care systems. CKD patients with type 2 DM ideally should be referred to the nephrologist as early as kidney disease has been diagnosed to exclude nondiabetic kidney disease requiring specific treatment. Regular follow-up is recommended, minimally yearly to ideally quarterly per year if CKD continues to progress (Fig. 31.2). However, with the shortage of nephrologists in many countries, if nephrologists were dedicated just to DM patients, lack of care for other renal disease patients would easily result if these recommendations were enforced. Consequently, general care providers often have to compensate for the lack of nephrologists. This includes knowledge of the medical issues involved in DM at each stage of CKD and the therapeutic interventions required (Fig. 31.3).

METABOLIC CONTROL

Glycemic control has a beneficial impact on prevention of CKD and preservation of renal function in type 1 DM as well as in type 2 DM (see Chapter 30). However, advancing CKD causes insulin resistance, impaired glucose tolerance, and hyperglycemia because a circulating factor interferes with the action of insulin. Because the insulin inhibitor is dialyzable, insulin resistance diminishes after the start of dialysis. At the same time, the half-life of insulin is prolonged. Furthermore, the potential for hypoglycemia with both oral agents and insulin increases in the presence of CKD (with the exception of gliquidone and glimepiride). Self-monitoring of blood glucose concentration is therefore imperative.

Ideally, reversal of DN through euglycemia and restoration of normal insulin secretion and action should be the goal. Thus, in type 1 DM, a pancreas transplant alone can induce regression of moderate DN lesions in native kidneys, but only during a period of 10 years after transplantation.³ Pancreas transplantation at the time of renal transplantation has been shown to prevent or to slow the development of DN in the transplanted kidney.

The choice of therapeutic approaches to glycemic control depends on the CKD stage (Fig. 31.4), the risk for hypoglycemia, and the patient's personal choice. Metformin has been used in low doses in patients with glomerular filtration rate (GFR) as low as 30 to 60 ml/min. It should not be used at a GFR below 30 ml/min, given the risk for lactic acidosis. As renal function can deteriorate abruptly, it is better to avoid metformin once serum creatinine concentration rises above 1.5 mg/dl (132 μ mol/l) in men and above 1.3 mg/dl (117 μ mol/l) in women. Insulin secretagogues (sulfonylurea and meglitinides) can be associated with hypoglycemia, with occurrence rates reported from 10% to 35%. These can be severe and long lasting in those receiving sulfonylureas, requiring hospitalization for treatment. Glycosidase inhibitors are short acting; because they interfere with the absorption of sucrose or starch; patients taking these agents need to use dextrose tablets or glucose gels to treat hypoglycemia. Glycosidase inhibitors are contraindicated in renal failure. Thiazolidinediones are associated with weight gain, in part from fluid retention but also due to nonfluid gains. In patients at risk for congestive heart failure, these should be avoided. There is also concern about increased bone fracture rates in patients using thiazolidinediones, which could potentiate CKD-related bone disease.⁴

Insulin regimens are the most commonly used to control glycemia in CKD. Given the increasing half-life of insulin as

Figure 31.1 Percentage of incident patients with end-stage renal disease (ESRD) due to diabetes, by year. Diabetes was the primary cause of end-stage renal disease (ESRD) in 58% of new patients in Malaysia in 2006 and 50% of those in Mexico. In a majority of reporting countries, 20% to 44% of new patients have this primary diagnosis. Countries with the lowest reported rates of ESRD due to diabetes include Romania, Russia, the Netherlands, Norway, Uruguay, and the United Kingdom (England, Wales, and N. Ireland), each with 12% to 19%. (Source: USRDS slides 2008.)

CKD progresses, the risk for hypoglycemia increases. Consequently, multiple daily injections or continuous insulin infusion per pump, by which insulin doses can be more closely regulated, would seem optimal. However, ideal insulin therapies remain undefined in CKD, given a paucity of pharmacokinetic studies that could guide insulin adjustment on the basis of GFR. It is also unclear whether intermediate or longer acting

insulins should be avoided and rapid-acting analogues used instead. The rapidly acting insulin analogues lispro and aspart exhibit similar pharmacokinetics in CKD patients as in patients with normal GFR. The same is true for detemir, but so far no clinical data on its use in CKD patients are available.⁵ Glargine has been shown to reduce hypoglycemia in hemodialysis (HD) patients.

Standard Care and Target Values Proposed for CKD Patients with Diabetes Mellitus		
Parameter	CKD 3/4	CKD 5 and 5D
Metabolic control		
glycosylated hemoglobin preferred agents	> 6.5 – 7.5 g% meglitinides/sulfonyl ureas/insulin	> 7.0-8.0 g% insulin
Blood pressure		
preferred agents	130/80 mmHg ACE/ARB's	np/Betablockers
Lipid treatment		
LDL cholesterol preferred agents	<100 mg/dl statins	np np/ns
Anemia treatment		
Hemoglobin level preferred agents	11.0 – 12.0 g/dl iron/ESA	11.0 – 12.0 g/dl (avoid >13) ESA/iron
Vitamin D supplements	Vit. D3/1.25-OHD	1.25 OHD/Vit. D3
Supportive treatment		
Smoking cessation	++	np
hypoglycemia awareness	++	+++
Lowdose aspirin	++	+/np
Exercise (daily/weekly)	+	+
Foot care	+++	+++
Prevention of falls	+	+++

Figure 31.3 Standard care and target values proposed for CKD patients with diabetes mellitus. For details, see text. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ESA, erythropoiesis-stimulating agent; LDL, low-density lipoprotein; NP, not proven; NS, not significant; +/++/+++, moderately/very/highly indicated.

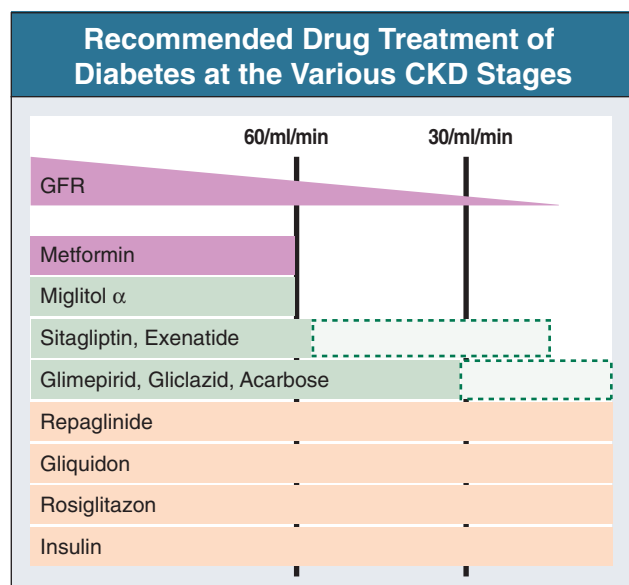

Figure 31.4 Recommended drug treatment of diabetes at the various CKD stages. GFR, glomerular filtration rate. Hatched green boxes indicate missing data.

Insulin requirements decrease further in HD patients, particularly in those with residual diuresis (<500 ml/day), insulin requirement often decreases by 30%. Two doses of an intermediate-acting insulin plus one preprandial rapidly acting insulin dose can usually achieve reasonable control. In peritoneal dialysis (PD) patients, intraperitoneal insulin is more physiologic than subcutaneous, as portal absorption of insulin may better mimic the endogenous insulin effect. Insulin requirements typically increase by 200% to 300% in this situation.⁵

BLOOD PRESSURE CONTROL

Blood pressure control is critical for primary and secondary prevention of renal disease and CVD in DM. At any given level of GFR, blood pressure tends to be higher in diabetic than in nondiabetic patients with CKD. Generally recommended blood pressure targets are 130/80 mm Hg, with recognition that in specific ethnic groups, 120/70 mm Hg may be a more appropriate target for decreasing renal disease progression. In diabetics with CKD, it will typically take three or four drugs to accomplish this, starting with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), then a diuretic, calcium channel blocker, β -blocker, or the recently licensed renin inhibitors.⁷

As discussed in Chapter 30, ACE inhibitors or ARBs are obligatory unless there are contraindications (e.g., an acute increase in serum creatinine of 50% or more; renal artery stenosis; hypovolemia; congestive heart failure; or hyperkalemia resistant to corrective maneuvers, such as administration of loop diuretics, dietary potassium restriction, or correction of metabolic acidosis). An increase in serum creatinine of 10% to 20% is expected and should not deter the administration of ACE inhibitors or ARBs. However, in patients with CKD stage 5, administration of ACE inhibitors may lower GFR to such an extent that dialysis becomes necessary. At this stage, these drugs are therefore no longer the first choice. However, if a patient is already established on an ACE inhibitor or ARB, these drugs should be continued in advanced renal failure unless there has been an

abrupt recent increase in serum creatinine. For example, in the Irbesartan in Diabetic Nephropathy Trial (IDNT),⁸ administration of ARBs extended the time until patients required dialysis.

β -Blockers can suppress the symptoms of hypoglycemia, which is a concern, given the propensity of diabetics with CKD for hypoglycemia.

Because of their marked propensity to retain salt, patients with DN are prone to development of hypervolemia and edema. Therefore, dietary salt restriction and administration of loop diuretics are usually indicated.

LIPID CONTROL

Data on the effects of lipid control in patients with DM and CKD are sparse. Triglyceride and low-density lipoprotein cholesterol levels are generally higher and high-density lipoprotein levels lower than in nondiabetics in type 2 DM.⁹

In diabetic patients with early CKD, secondary analyses support the use of statins. In the Heart Protection Study, patients with DM and CKD who received statins had a 23% decrease in cardiovascular risk with an absolute event reduction of 80%.¹⁰ In the Cholesterol And Recurrent Events (CARE) study, risk reduction for coronary events was similar in nondiabetic and diabetic patients with CKD (creatinine clearances <75 ml/min).^{11,12} A combined analysis of various studies of statins in diabetics with early CKD (Pravastatin Pooling Project, CARE, and Long-term Intervention with Pravastatin in Ischemic Disease [LIPID]) showed that the risk reduction for cardiovascular events was 6.5% and thus exceeded that observed in diabetics without CKD or nondiabetics.⁹

In HD patients with type 2 DM, the addition of 20 mg of atorvastatin did not decrease cardiovascular death, nonfatal myocardial infarction, or stroke despite a 40% decrease in low-density lipoprotein cholesterol levels.¹³ If strokes were omitted from the analyses, there was a significant decrease in cardiac events. Observational data in dialysis patients also suggest that statins decrease total and cardiovascular mortality.^{8,14} However, these studies were not limited to diabetics; 60%¹⁴ and 43%⁸ of the patients receiving statins were diabetic.

As metabolism of different statins varies, the need to modify doses as GFR changes should be kept in mind. Atorvastatin can be given in doses up to 80 mg/day for those on HD and PD. Fluvastatin can also be given in doses up to 80 mg/day. Pravastatin should be limited to 10 mg, as active metabolites can accumulate, although in the Pravastatin Pooling Project, doses of up to 40 mg were safely used down to GFR of 30 ml/min per 1.73 m². Simvastatin, 20 mg/day, can be safely used, with 40-mg daily doses in the Heart Protection Study used safely even in stage 3 CKD. Rosuvastatin should be limited to not more than 10 mg daily when GFR falls below 30 ml/min per 1.73 m². Ezetimibe can be safely used in renal impairment, as can bile acid sequestrants, but the potential effect on absorption of other prescriptive drugs, particularly with the bile acid sequestrants, should be kept in mind. Fenofibrate doses should be reduced by one third in CKD stage 2, reduced by two thirds in CKD stages 3 and 4, and avoided in CKD stage 5. Gemfibrozil can be safely used, although in PD, elevated CPK levels have been reported at usual doses. Sustained-release niacin should be decreased by 50% at CKD stage 5.⁹

DIET AND MALNUTRITION

Diabetic patients with renal failure are often severely catabolic and tend to develop malnutrition (see Chapter 83). This risk is

particularly high during periods of intercurrent illness and fasting but may also be the result of ill-advised recommendations to restrict protein intake. Anorectic obese patients with type 2 diabetes and advanced CKD often undergo massive weight loss, leading to normalization of fasting glucose concentration and even of hyperglycemia after a glucose load. Low muscle mass because of wasting is an important reason for misjudging the severity of renal failure, leading, for example, to delayed start of RRT. Therefore, creatinine clearance should be measured, or at least an estimate of GFR by use of the Cockcroft-Gault or the Modification of Diet in Renal Disease (MDRD) study formula should be obtained rather than relying on serum creatinine.

ANEMIA

Anemia occurs at an earlier stage of CKD in DM patients and is often more severe.^{15,16} However, confounding these data is the fact that in diabetes, anemia can develop even at a normal GFR. At GFR of 30 to 60 ml/min, 20% of diabetics are anemic.¹⁷ If a hemoglobin cutoff of 11 g/dl is used, 20% to 31% of patients with diabetes and CKD stage 3 or higher are anemic; at GFR below 50 ml/min per 1.73 m², this increases to 27% to 42%.¹⁷

In a meta-analysis of several community longitudinal studies, anemia was found to be a risk factor for adverse cardiovascular outcomes as well as for all-cause mortality in those with diabetes and CKD.¹⁸ In the Atherosclerosis Risk In Communities (ARIC) study, anemia alone was a risk factor; but when anemia and CKD were both present, a synergistic risk for stroke and coronary disease was found, compared with each risk factor alone. In those with DM, microvascular as well as macrovascular disease of the coronary circulation or more severe left ventricular hypertrophy could increase susceptibility to ischemia induced by anemia.¹⁹ Erythropoietin-dependent anemia is also associated with autonomic neuropathy, which itself is a risk factor for a cardiovascular event. It is also associated with impaired sleep, impaired cognitive function, decreased exercise tolerance, and a general decrease in quality of life. Finally, anemia predicts a faster rate of progression of renal disease.¹⁶

Small studies have suggested that treatment with erythropoietin (EPO) can effectively treat anemia associated with CKD in diabetes, but in higher dosages compared with nondiabetic patients. Quality of life and well-being improve. The recent TREAT-study randomly assigned 2012 diabetics with CKD stage 3 to 4 to darbepoetin alfa to achieve a hemoglobin level of approximately 13 g per deciliter and 2026 patients to placebo, with rescue darbepoetin alfa when the hemoglobin level was less than 9.0 g per deciliter. The higher target hemoglobin failed to reduce death, cardiovascular or renal events and was associated with an increased risk of stroke, supporting a target hemoglobin of 11–12 g/dl in such patients (see also Chapter 79).²⁰

MINERAL AND BONE DISEASE

Diabetic patients with CKD develop secondary hyperparathyroidism at a slower rate than nondiabetics do and are predisposed to low-turnover (adynamic) bone disease (see Chapter 81). Adynamic bone disease in turn is a recognized risk factor for cardiovascular calcification (see Chapters 78 and 81), as is diabetes itself. Thus, it is not surprising that CKD and diabetes appear to exert additive effects on cardiovascular calcification. At GFR of about 50 ml/min, 100% of diabetics exhibit coronary calcification and 20% have calcification of the aortic wall.

Prevention of diabetic foot complications

- Identification of patients at risk
- Education about foot care
- Regular examination of the feet at clinic
- Provision of appropriate footwear
- Provision of podiatry services

B

Figure 31.5 The diabetic foot. **A**, Gangrenous ulcers in a diabetic caused by a combination of large- and small-vessel disease and neuropathy. **B**, Prevention of diabetic foot complications.

Preventive and therapeutic approaches to CKD-related bone and mineral disease do not differ substantially between diabetics and nondiabetics (see Chapter 81). However, given the increased prevalence of low-turnover bone disease in diabetics with CKD, care should be taken to avoid calcium loading. These patients also appear to accumulate aluminum more readily and are more susceptible to aluminum-induced bone disease. Aluminum-containing phosphate binders should always be avoided in the diabetic patient with advanced CKD.

EXTRARENAL COMPLICATIONS CAUSED BY MICROANGIOPATHY AND MACROANGIOPATHY

Even the asymptomatic diabetic patient with advanced CKD must be monitored at regular intervals for timely detection of microvascular and macrovascular complications (ophthalmologic examination at half-yearly intervals; cardiac and angiologic status including imaging of the carotid artery yearly; foot inspection preferably at each visit). In particular, problems related to the diabetic foot are a major cause of hospital admission and nontraumatic amputation (Fig. 31.5A). Diabetic microangiopathy of the foot is frequently complicated by diabetic and uremic polyneuropathy, both of which respond poorly to conventional treatments (see Chapter 82). The situation is further aggravated by an increased risk of diabetics for infections, in particular staphylococcal infection.

Measures to prevent diabetic foot complications are shown in Figure 31.5B.

PREVENTION AND TREATMENT OF CARDIAC DISEASE

In diabetics, the likelihood of death due to cardiovascular events far exceeds that of reaching ESRD, and thus the population of

diabetics on dialysis represents a “positive selection.”²¹ In type 2 DM, the annual transition rate through the various stages of nephropathy was far lower than the annual mortality rate (see Fig. 31.2).²² Similar observations have been made in the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) trial in type 1 diabetics²³ and in particular in the Steno-2 population, in which 27 deaths (14 due to CVD) occurred during a mean follow-up of 7.8 years, whereas mean GFR decreased by about 30 ml/min per 1.73 m² and no subject reached ESRD.²⁴ Two studies designed to evaluate the effect of intensive treatment on vascular complications, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease: Preterax and Diamcron MR Controlled Evaluation (ADVANCE) trials, substantiate the high incidence of fatal cardiovascular events compared with the low progress to advanced renal failure.^{25,26} Once a diabetic has reached ESRD, the cardiovascular mortality rate is still excessive. For example, in diabetic dialysis patients with an acute coronary syndrome, mortality is 42% after 1 year and 75% after 5 years of treatment.²⁷ This may relate to the fact that in diabetics, coronary heart disease is often amplified by the coexistence of more severe left ventricular hypertrophy, congestive heart failure, disturbed sympathetic innervation, and microvascular disease.

How and when best to intervene in the progressive course of CVD in diabetics with CKD has not been precisely defined. Recent American Diabetes Association recommendations underline the role of smoking cessation, lifestyle changes, and medical treatment in patients with diabetes and known CVD.²⁸ These risk factors may be even more critical in advanced CKD, given the multiple consequences of a single risk factor such as smoking on blood pressure, lipids, and glucose, which further amplify the independent risks of these factors in patients with both diabetes and CKD.

In the absence of data, recommendations for the formal workup of coronary heart disease in diabetic patients with CKD should be no different from those for nondiabetic CKD patients (see also Chapter 78).²⁹ The rate of all coronary revascularization procedures in the ESRD population has risen in the last 10 years.²¹ In nondialysis patients, both coronary intervention and bypass surgery can be associated with significant risk of acute renal deterioration, which must be weighed against the potential outcome benefits in the individual patient. In general, to preserve residual renal function, bypass grafting might be favored in nondialysis CKD stages, whereas interventional stenting procedures might be assumed to be more appropriate for dialysis patients with limited life span, if risks of cerebrovascular complications are assessed and treated adequately. For further discussion of whether to use coronary stenting or bypass grafting in diabetics with CKD, refer to Chapter 78.

RENAL REPLACEMENT THERAPY

As discussed in Chapter 86, whereas the mean estimated GFR at the start of dialysis is 7 to 8 ml/min per 1.73 m² in most dialysis populations, a higher threshold is usually used in diabetics (serum creatinine >6 mg/dl [530 μmol/l] or estimated GFR <15 ml/min) as they tend to tolerate uremia poorly and are frequently troubled by sodium retention and fluid overload.

Selection of the mode of dialysis is discussed in Chapter 86; advantages and disadvantages of each technique are outlined in Figure 31.6. Death rates of diabetic patients on HD and PD have decreased substantially but remain higher than rates of

Comparison of Dialysis Options for the Diabetic Patient				
Parameters	Peritoneal Dialysis		Hemodialysis	
	Advantages	Disadvantages	Advantages	Disadvantages
Technique	No need for vascular access, better preservation of residual renal function	Low technique survival rate, high hospitalization rate, higher rate of infections	Better technique survival rate, lower hospitalization and infection rate	Frequent difficulty in obtaining good vascular access
Blood pressure	Good control, slow ultrafiltration, and fewer episodes of cardiovascular instability			Difficult control, more frequent hypotensive episodes (in particular, in patients with autonomic neuropathy)
Nutritional factors	Fewer dietary restrictions	Excessive weight gain, poor nutrition		Difficulty with fluid and dietary restrictions
Biochemical and metabolic control	Steady-state biochemical parameters	Worsening of blood glucose control and hyperlipidemia, increased insulin requirements	Efficient solute and water extraction	
Social factors	Maintains independence		Better medical surveillance	In most diabetics, cannot be performed at home

Figure 31.6 Comparison of dialysis options for the diabetic patient.

nondiabetics on both modalities.³⁰ Younger diabetics treated with peritoneal dialysis have a significantly lower risk of death than do those treated with hemodialysis during early years of dialysis. Technique failure is higher in diabetics compared with nondiabetics and in peritoneal dialysis compared with hemodialysis. Patients with diabetes have higher rates of hospital admission than do nondiabetics on hemodialysis or peritoneal dialysis, with significantly higher rates in peritoneal dialysis compared with hemodialysis.³⁰ Peritoneal dialysis-associated glucose loading in diabetics can be overcome by replacing glucose solutions in part by amino acid solutions and polyglucose. Loss of solute and water transport often limits long-term use of peritoneal dialysis to 3 to 5 years. Switching to hemodialysis should be considered before volume overload or uremic symptoms occur. In diabetics on peritoneal dialysis, maltose and polyglucose, present in dialysis solutions, affect glucose dehydrogenase-based glucose meters. Glucose meters for home blood glucose monitoring should be changed to those using a glucose oxidase test method.³¹

Higher levels of comorbidity predict excess mortality in diabetic dialysis patients.³² Because infectious complications are the leading cause of hospitalization and the second most frequent cause of death in diabetes, prevention of fistula infections and the diabetic foot syndrome is essential. Vaccination should be considered to prevent pneumonia and influenza (see Chapter 80). Protection from falls may lower risk of fractures and their fatal consequences.

Diabetics with ESRD of all age groups significantly benefit from kidney transplantation, although only a minority of older

diabetics will be eligible for transplantation, cardiovascular comorbidity being the most common reason for exclusion.³³ If renal transplantation is not immediately available, peritoneal dialysis is an option for bridging to transplantation. Peritoneal dialysis is associated with longer protection of residual renal function, better blood pressure control, and higher level of quality of life, and it preserves blood vessels for future vascular access.³⁴

Finally, there is evidence that ESRD rates may be stabilizing in diabetics and that efforts to reduce progression may start to show benefits.³⁵

Normal Blood Pressure Control and the Evaluation of Hypertension

William J. Lawton, Friedrich C. Luft, Gerald F. DiBona

NORMAL BLOOD PRESSURE CONTROL

Systemic arterial blood pressure (BP), or the pressure of the blood within the arteries exerted against the arterial wall, is produced by the contraction of the left ventricle (producing blood flow) and the resistance of the arteries and arterioles. Systolic blood pressure (SBP), or maximum BP, occurs during left ventricular systole. Diastolic blood pressure (DBP), or minimum BP, occurs during ventricular diastole. The difference between SBP and DBP is the pulse pressure.¹ The mean arterial pressure (MAP) is clinically defined as the DBP plus one third of the pulse pressure.

Blood flow (Q) is defined by Ohm's law and varies directly with the change in pressure (P) across a blood vessel and inversely with the resistance R (defined as $Q = P/R$). Rearrangement shows that pressure varies directly with blood flow and resistance ($P = QR$). Ohm's law suffices for an overall view of the circulation. However, for a more detailed picture of the resistance to flow in any given vessel, the relationship of Hagen-Poiseuille should be applied:

$$Q = \Delta P \times (\pi r^4 / 8L) \times (1/\eta)$$

Here, r is the radius of the pipe, L is its length, and η is the coefficient of viscosity. Thus, as the lumen of a vessel decreases, the pressure will increase to the fourth power of the radius for the same blood flow. In other words, a 50% reduction in radius will require a 16-fold increase in pressure to maintain equivalent flow.

Normal BP is controlled by cardiac output and the total peripheral resistance and is dependent on the heart, the blood vessels, the extracellular volume, the kidneys, the nervous system, humoral factors, and cellular events at the membrane and within the cell (Fig. 32.1). Cardiac output is determined by the stroke volume (liters/minute) and the heart rate. In turn, stroke volume is dependent on intravascular volume regulated by the kidneys as well as on myocardial contractility. Myocardial contractility is a complex function involving sympathetic and parasympathetic control of heart rate, intrinsic activity of the cardiac conduction system, complex membrane transport and cellular events requiring influx of calcium that lead to myocardial fiber shortening and relaxation, and effects of humoral substances (e.g., catecholamines) on stimulating heart rate and myocardial fiber tension.

Total peripheral resistance is regulated by complex interactive mechanisms, including baroreflexes and sympathetic nervous system activity, response to neurohumoral substances and

endothelial factors, myogenic responses, and intercellular events mediated by receptors and mechanisms for signal transduction.² For example, there are two major neural reflex arcs. Baroreflexes are derived from (1) high-pressure baroreceptors in the aortic arch and carotid sinus and (2) low-pressure cardiopulmonary baroreceptors in ventricles and atria. These receptors respond to stretch (high pressure) or filling pressures (low pressure) and send tonic inhibitory signals to the brainstem (nucleus tractus solitarius). If BP increases and tonic inhibition increases, inhibition of sympathetic efferent outflow occurs and decreases vascular resistance and heart rate. However, if BP decreases, less tonic inhibition ensues from the baroreflexes and both heart rate and peripheral vascular resistance increase, thereby increasing BP.

The brainstem cardiovascular centers are localized in the dorsomedial medulla. Neural afferents from cranial nerves IX and X are integrated in the nucleus tractus solitarius (NTS). From here, vasoconstriction and increased heart rate are mediated through the caudal and rostral ventrolateral medulla by the sympathetic nervous system. Also, NTS efferents communicate with the nucleus ambiguus (vagal nucleus) to decrease heart rate through the vagus nerve. In addition, the neural control of renal function produces alterations in renal blood flow, glomerular filtration rate (GFR), excretion of sodium and water, and release of renin and other vasoactive substances. These factors, in turn, have effects on the regulation of intravascular volume, vascular resistance, and BP.³

Numerous vasoactive substances have effects on blood vessels, the heart, the kidneys, and the central nervous system and often counterbalance one another. Some of these substances and membrane and cellular events are shown in Figures 32.2 and 32.3. The renin-angiotensin system (RAS) and aldosterone are extremely important effector systems that regulate both volume and peripheral vascular resistance as shown in Figure 32.4. Angiotensin II (Ang II) constricts vascular smooth muscle; stimulates aldosterone secretion; potentiates sympathetic nervous system activity; stimulates salt and water reabsorption in the proximal tubule; stimulates prostaglandin, nitric oxide, and endothelin release; increases thirst; and is a growth factor. When it is present in excess, Ang II can induce remodeling, inflammation, and vasculopathy. The kallikrein-kinin system produces vasodilator kinins that in turn may stimulate prostaglandins and nitric oxide and counterbalance the RAS (see Fig. 32.4). Aldosterone mediates changes in sodium channels in distal renal tubular epithelium, leading to sodium retention and potassium excretion. The hormone also functions as a growth factor and exerts complex nongenomic and genomic events through the mineralocorticoid receptor in vascular cells and in the heart.

Figure 32.1 Some factors involved in the regulation of blood pressure.

Plasma concentrations of renin and aldosterone are both inversely related to salt intake and are influenced by various medications. Aldosterone is measured by radioimmunoassay. Plasma renin is measured as plasma renin activity based on the generation of angiotensin in the presence of angiotensin-degrading enzyme inhibitors or as plasma renin concentration by immunoassay.

A second major effector system is the sympathetic nervous system. Nerve endings release norepinephrine. This potent neurotransmitter is a vasoconstrictor through α -adrenergic receptor-mediated mechanisms. Vascular cells, renal cells, and many other cells (e.g., adipocytes) are innervated. Epinephrine increases heart rate, stroke volume, and SBP through α - and β -adrenoceptors. The hormone is released from the adrenal medulla. There is compelling evidence that increased sympathetic tone has long-term influences on cardiovascular regulation and that disturbed sympathetic tone may cause hypertension. In the kidneys, sympathetic nerves are important mediators of renin release. Furthermore, innervation of each individual nephron has an important bearing on sodium reabsorption. Thus, the sympathetic nervous system regulates both effective circulating fluid volume and peripheral vascular resistance.

Prostaglandin E and prostacyclin act to counterbalance vasoconstriction by Ang II and norepinephrine. Two endothelium-derived factors have opposite effects on the blood vessels: nitric oxide is a vasodilator, whereas the endothelins are

vasoconstrictors. Natriuretic peptides induce vasodilation, and natriuresis and inhibit other vasoconstrictors (RAS, sympathetic nervous system, and endothelin). Renalase is a recently discovered flavin adenine dinucleotide-dependent amine oxidase that is secreted by the kidney, circulates in the blood, and modulates cardiac function and systemic BP. It acts by metabolizing catecholamines, and its discovery should further our understanding of sympathetic regulation.^{4,5} Urotensin II is a cyclic vasoactive peptide expressed in many organ systems and is inversely related to norepinephrine and brain natriuretic peptide. High plasma levels of urotensin II, a cyclic vasoactive peptide predict reduced cardiovascular complications in patients with chronic kidney disease (stages 2 to 5).⁶ Heme oxygenase (HO) has recently been found to suppress arachidonic acid metabolism and to decrease BP in several models of hypertension. The HO system may have an important role in regulating BP and kidney function.⁷

Postreceptor intracellular signaling events also regulate peripheral vascular resistance. For instance, the small guanosine triphosphatase Rho and its effector, Rho-associated kinase (Rho-kinase) are important in Ca^{2+} -independent regulation of smooth muscle contraction. The Rho, Rho-kinase pathway modulates the level of phosphorylation of the myosin light chain of myosin II, mainly through inhibition of myosin phosphatase, and contributes to agonist-induced Ca^{2+} sensitization in smooth muscle contraction. Rho, Rho-kinase mechanisms also participate in a variety

Vasoactive Substances that Modulate Blood Pressure		
Vasoactive Substances		
Group	Compound	Cellular Effects
Catecholamines	Norepinephrine, epinephrine, dopamine	Adrenergic receptors (α_1 , α_2 , β_1 , β_2) causing protein phosphorylation and increased intracellular calcium via G proteins linked to ion channels or second messengers (cyclic nucleotides, phosphoinositide hydrolysis)
Renin-angiotensin system (RAS)	Angiotensin II (Ang II)	Angiotensin receptors (AT ₁ , AT ₂ , AT ₄) causing increased intracellular calcium and protein phosphorylation via second messenger, phosphoinositide hydrolysis, and activated protein kinases Aldosterone stimulation
Mineralocorticoids	Aldosterone	Genomic: Binds to cytoplasmic mineralocorticoid receptor (MR), translocates to nucleus, modulates gene expression, signals transduction and effectors (S _g K, CHIF, K-Ras) which increases transport proteins (increasing ENaC number and open probability) Non-Genomic: Effects via separate membrane or cytosolic proteins
Kallikrein-kinin system	Bradykinin	Bradykinin receptors (B ₁ , B ₂), B ₂ -G protein coupling cause activation of phospholipase C, increased inositol phosphates, and intracellular calcium
Arachidonic acid products	Prostaglandins: prostaglandin E, prostacyclin, thromboxanes Lipoxygenase enzyme products: leukotrienes, hydroxyeicosatetraenoates	Nine prostaglandin receptors coupled to G proteins: (e.g., PGI ₂ [Receptor IP], PGE ₂ [Receptors EP ₁ , EP ₂]); PGF _{2α} (Receptor FP)
Endothelium-derived factors	Endothelium-derived relaxing factor (nitric oxide) Endothelins (ET-1, ET-2, ET-3)	Increased levels of cyclic guanosine monophosphate cause activation of protein kinases G proteins activate phospholipase C and L-type calcium channels Class 2 G protein-coupled receptor
Natriuretic peptides (NPs)	Atrial, brain, and C-type NPs	Activation of three receptor types; further effects mediated by cGMP
Posterior pituitary hormones	Arginine vasopressin	Vasopressin receptors (AVPR 1A; AVPR 1B) mediated by second messenger system, phosphatidyl, inositol/calcium; AVPR2 effects via adenylate cyclase (cAMP)
Other substances	Acetylcholine, adenosine, insulin, neuropeptide Y, serotonin, sex hormones (estrogens, progesterone, androgens), glucocorticoids, other mineralocorticoids, substance P, vasopressin, reninase, heme oxygenase 1

of the cellular functions of nonmuscle cells, such as stress fiber formation, cytokinesis, and cell migration. A specific pharmacologic Rho-kinase inhibitor (fasudil) has been developed that may have utility in treating cerebral artery spasm and other forms of severe vascular constriction.⁸

Guyton and Hall¹ have analyzed the temporal sequence for adjustment of BP. In their analysis, central nervous system mechanisms (e.g., baroreflexes) provide regulation of the circulation within seconds to minutes. Other mechanisms, such as the renin-angiotensin-aldosterone system and fluid shifts, occur during minutes to hours. It was once considered that only the kidneys have the ability for long-term adjustments in BP, predominantly through regulation of extracellular volume¹ (Fig. 32.5); but recent evidence indicates that long-term afferent baroreflex stimulation by an electrical device can lower BP chronically in several different animal models.⁹ The critical role for the kidney in the long-term control of BP received strong support from kidney cross-transplantation experiments. Nevertheless, precisely such experiments have recently shown that both intrarenal and extrarenal mechanisms are involved.¹⁰

DEFINITION OF HYPERTENSION

Concepts

BP is normally distributed in the general population. Thus, any definition of hypertension is arbitrary. Hypertension is usually asymptomatic; patients are more typically symptomatic from the sequelae of hypertension or its treatment. Hypertension may be defined by its associated morbidity and mortality, as increases over arbitrary cutoff points, or by thresholds defining therapeutic benefit.

Blood Pressure in Relation to Morbidity and Mortality

The first approach defines hypertension by relating BP levels to the risk of morbidity and mortality. The association of SBP and DBP with cardiovascular and renal complications is continuous over the entire BP range.¹¹ Observational studies involving more than 1 million individuals have found that death from both ischemic heart disease and stroke increases progressively and linearly from BP as low as 115 mm Hg SBP and 75 mm Hg DBP upward (Figs. 32.6 and 32.7). The increased risks are present in all age groups ranging from 40 to 89 years. For every increase of 20 mm Hg SBP or 10 mm Hg DBP, the mortality from both ischemic heart disease and stroke doubles. On the basis of these data, the Joint National Committee (JNC) 7 report introduced a new classification that includes the term *prehypertension* for those with BP ranging from 120 to 139 mm Hg SBP or 80 to 89 mm Hg DBP.¹² The designation prehypertensive identifies persons in whom early intervention (lifestyle) could reduce BP or avoid further increases. Since JNC 7, the Writing Group of the American Society of Hypertension (WG-ASH) has proposed a new definition of hypertension not based on BP values alone but considering hypertension as a complex cardiovascular disorder. The new definition includes target organ damage, early disease markers, and cardiovascular risk factors (Fig. 32.8).¹³ Although it is not uniformly agreed on, the risk-based approach

Figure 32.6 Ischemic heart disease (IHD) mortality rate in each decade of age versus usual blood pressure at the start of that decade. **A**, Systolic blood pressure. **B**, Diastolic blood pressure. Floating absolute risk corrects for the absolute death rate within a particular community. The size of the squares correlates inversely with the variance of the data collected for that data point. CI, confidence interval. (Reprinted with permission from reference 11.)

seeks to identify individuals with an increased likelihood of future cardiovascular events at any BP level. The WG-ASH stage 1 can include the “prehypertension” in JNC 7.

Elevation of Blood Pressure by Arbitrary Cut Points

A second approach defines hypertension by the frequency distribution within a population. This statistical approach will arbitrarily designate values above a certain percentile as hypertensive. This method is used in defining hypertension in children. The values defining hypertension will vary according to age, gender, body size, and race.¹⁴ This frequency distribution method is not helpful for determining a value for initiation of antihypertensive treatment but is useful in epidemiologic studies, for example, defining the prevalence of hypertension in various age groups or the changing prevalence of hypertension in a given population over time. The prevalence of hypertension in adults in the United States, defined as BP of 140/90 mm Hg or higher, has increased progressively from 11% of the population in 1939 to 29.3% in 2004.¹⁵ The prevalence of hypertension in six European countries has been reported at 44%, and it is 66.3% in those older than 60 years.¹⁶

Threshold of Therapeutic Benefit

The third concept for defining hypertension is derived from randomized trials that have demonstrated reductions in mortality

and morbidity. As a result of these clinical trials, consensus has been reached on intervention levels for moderate and severe hypertension but not for lower levels of hypertension. The Hypertension Optimal Treatment (HOT) study showed benefits of lowering BP to 138/83 mm Hg in hypertensive subjects in the absence of diabetes mellitus, chronic kidney disease, coronary artery disease risk, or target organ damage. For subjects with these complications, a treatment goal below 130/80 mm Hg is recommended (JNC 7).

Operational Definitions

The European Society of Hypertension (ESH) divides normotension into three categories (optimum, normal, and high-normal) and describes hypertension as mild, moderate, or severe (Fig. 32.9).^{17,18} The ESH also gave values for automated 24-hour BP measurements, divided into daytime and nighttime.

In the United States, the JNC 7 defined hypertension for individuals 18 years of age and older.¹² The Committee settled on normal, prehypertension, and stage 1 and stage 2 hypertension (Fig. 32.10). For children, the JNC considers that BP at the 95th percentile or higher at each age is elevated.

Clinicians evaluate hypertensive patients and treatment goals on the basis of overall cardiovascular risk factors, not by BP alone. Age, gender, and ethnicity cannot be altered and are

Figure 32.7 Stroke mortality rate in each decade of age versus usual blood pressure at the start of that decade. **A**, Systolic blood pressure. **B**, Diastolic blood pressure. WG-ASH Definition and Classification of Hypertension						
	Blood Pressure Classification	Pressure Elevations	Cardiovascular Disease*	Cardiovascular Risk Factors	Early Disease Markers	Target Organ Disease
Normal	Normal	Normal or rare	or None	None or few	None	None
Hypertension						
Stage 1	Occasional	Intermittent	or Early	Several	Usually present	None
Stage 2	Sustained		or Progressive	Many	Overtly present	Early signs present
Stage 3	Marked and sustained		or Advanced	Many	Overtly present with progression	Overtly present with or without cardiovascular disease events

Figure 32.8 Working Group–American Society of Hypertension (WG-ASH) definition and classification of hypertension. *Determined by constellation of risk factors, early disease markers, and target organ disease.

European Society of Hypertension Consensus Classification					
Conventional Blood Pressure Measurement*		Ambulatory Blood Pressure Measurement†			
Category	Boundaries	Measurement	P95‡	Normotension	Hypertension
Normotension		Ambulatory			
Optimum	<120/<80	24-h	132/82	<130/<80	>135/85
Normal	120–129/80–84	Daytime	138/87	>135/<85	>140/90
High-normal	130–139/85–89	Nighttime	123/74	<120/<70	>125/75
Hypertension		Self-recorded			
Grade I (mild)	140–159/90–99	Morning	136/85	<135/85	>140/90
Subgroup borderline	140–149/90–94	Evening	138/86	<135/85	>140/90
Grade II (moderate)	160–179/100–109	Both	137/85	<135/85	>140/90
Grade III (severe)	>180/>110				
Isolated systolic hypertension	>140/<90				
Subgroup borderline	140–149/<90				

Figure 32.9 European Society of Hypertension consensus classification. Blood pressure readings are in millimeters of mercury (mm Hg). *Consensus classification proposed by the European Society of Hypertension/European Society of Cardiology guidelines (see reference 17). †Classification proposed at the Eighth International Consensus Conference on Ambulatory Blood Pressure Measurement (Sendai, Japan, October 2001). ‡Mean of 95th percentiles in subjects who on conventional blood pressure measurement were normotensive in large-scale studies.

JNC 7 Classification of Blood Pressure for Adults (2003)		
BP Classification	SBP (mm Hg)	DBP (mm Hg)
Normal	<120	and <80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	≥160	or ≥100

Figure 32.10 The Joint National Committee (JNC) 7 classification of blood pressure for adults (2003). BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

important risk factors. However, cholesterol, high-density lipoprotein (HDL) cholesterol, smoking, control of diabetes, obesity, and left ventricular hypertrophy are potentially modifiable (Fig. 32.11).¹⁸ The cluster of risk factors that increase cardiovascular risk and are often associated with hypertension is termed the metabolic syndrome (Fig. 32.12). Decreased renal function is also recognized as an independent cardiovascular risk factor.¹⁹ The same is true for proteinuria, starting with the barely detectable amount of more than 6 mg/day albumin. Figure 32.13 gives the JNC 7 recommendations for follow-up of BP findings in a given individual.

Special Definitions

Prehypertension (High-Normal or Borderline Hypertension) Despite lack of uniform agreement, prehypertension is most usefully defined as BP of 130 to 139/85 to 89 mm Hg (also called stage 2 prehypertension; stage 1 prehypertension, 120 to 129/80 to 84 mm Hg). An older definition of “borderline hypertension” defined individuals whose BP was sometimes above 140/90 mm Hg but would decrease to levels below this with rest. Estimates of prehypertension or borderline hypertension have ranged between 12% and 30% of the adult population. Individuals with prehypertension (stage 2) have a threefold

greater likelihood for development of sustained hypertension. During a 20-year follow-up, weight gains of 15 to 20 pounds (6.8 to 9.1 kg) in this group may be associated with a higher risk for development of sustained hypertension. Some of these individuals have a high cardiac output and increased catecholamine turnover. Borderline hypertension may represent an exaggeration of normal physiologic responses to stress. Individuals with prehypertension may have a greater frequency of obesity, abnormal lipids, and other cardiovascular risk factors, with twice the cardiovascular events compared with those with BP below 120/80 mm Hg.²⁰ Because all BP is “labile” (variable) and generally varies on a diurnal cycle, the term *labile hypertension* is not helpful and should not be used.

White Coat Hypertension White coat hypertension is defined as BP that is normal during usual daily activities but is hypertensive in a clinical setting. Normal pressures outside the physician’s office are determined by measurement with standard techniques or by ambulatory BP recordings. White coat hypertension can be seen at all ages, including the elderly. The white coat phenomenon is seen less frequently when a nurse or technician takes the BP rather than a physician. White coat hypertension is present in approximately 20% of hypertensive persons. Guidelines are available to assist in assessing patients with isolated clinic hypertension or isolated ambulatory hypertension.²¹

The significance and prognosis of white coat hypertension are unclear. Some studies show that the office- or clinic-induced increase in BP is benign. Other studies report that white coat hypertension is characterized by increases in left ventricular mass index at levels intermediate between normotensive and persistently hypertensive persons.²² White coat hypertensive patients have impaired diastolic function and higher levels of catecholamines, plasma renin activity, aldosterone, and low-density lipoprotein (LDL) cholesterol. There is also some evidence that subjects with white coat hypertension may be at increased risk for development of persistent hypertension.²² Thus, each patient with white coat hypertension needs evaluation for cardiovascular risk factors and correction of these, if present, as well as continued follow-up.

Figure 32.11 Absolute risk of cardiovascular disease during 5 years in patients by systolic blood pressure at specified levels of other risk factors. Reference category is a nondiabetic, nonsmoking woman aged 50 years with total cholesterol (TC) level of 4 mmol/l (155 mg/dl) and high-density lipoprotein (HDL) level of 1.6 mmol/l. Risks are given for systolic blood pressure (SBP) levels of 110, 120, 130, 140, 150, 160, 170, and 180 mm Hg. In the other categories, additional risk factors are added consecutively, for example, the diabetes category is a diabetic 50-year-old male cigarette smoker with a total cholesterol level of 7 mmol/l (270 mg/dl) and HDL level of 1 mmol/l (39 mg/dl). CVD, cardiovascular disease. (Reprinted with permission from reference 18.)

Common Definitions for Metabolic Syndrome	
Criterion	NCEP ATP III (3 or more criteria)
Abdominal obesity Men Women	Waist circumference >40 inches (>102 cm) >35 inches (>88 cm)
Hypertriglyceridemia	>150 mg/dL (≥ 1.7 mmol/l)
Low HDL Men Women	<40 mg/dL (<1.03 mmol/l) <50 mg/dL (<1.30 mmol/l)
Hypertension	$\geq 130/85$ mm Hg or on antihypertensive medication
Impaired fasting glucose or diabetes	>100 mg/dl (5.6 mmol/l) or taking insulin or hypoglycemic medication

Figure 32.12 Common definitions for the metabolic syndrome. (From reference 23.)

Recommendations for Follow-Up Based on the Initial Blood Pressure Measurements for Adults		
Initial Blood Pressure (mm Hg)*		Follow-Up Recommended
Systolic	Diastolic	
>130	>85	Recheck in 1 year
130–139	85–89	Recheck in 1 year; provide information about lifestyle modification
140–159	90–99	Confirm within 2 months
160–179	100–109	Evaluate or refer to source of care within 1 month
≥ 180	≥ 110	Evaluate or refer to source of care immediately or within 1 week, depending on clinical situation

Figure 32.13 Recommendations for follow-up based on the initial blood pressure measurements for adults. *If systolic and diastolic categories are different, follow recommendations for the shorter time for follow-up. The schedule for follow-up should be modified according to reliable information about past blood pressure measurements, other cardiovascular risk factors, or target organ disease.

Figure 32.14 Plot of clinic systolic and daytime ambulatory blood pressure to define four groups: normal, white coat hypertension, sustained hypertension, and masked hypertension. (From reference 24.)

Masked Hypertension Masked hypertension is defined as BP that is lower in the office or clinic compared with ambulatory BP. In one study, the 10-year risk of stroke and cardiovascular mortality in subjects with masked hypertension was similar to that of patients with sustained hypertension (Fig. 32.14).²²

Sustained Hypertension Sustained hypertension, also called persistent hypertension, defines individuals whose BP levels are elevated both inside and outside the clinic setting, including at home and during usual daily activities. Office BP readings are frequently higher in sustained hypertensives compared with their ambulatory BP.

Pseudohypertension Pseudohypertension is defined as “a condition in which the cuff pressure is inappropriately higher when compared to the intra-arterial pressure because of excessive atheromatosis and/or medial hypertrophy in the arterial tree.”²⁵ Pseudohypertension can be suspected by the “Osler maneuver,” in which the BP cuff is inflated above the SBP (detected by auscultation). If either the brachial or radial artery remains palpable, when pulseless, the patient is considered to be Osler maneuver positive. In general, patients with pseudohypertension have intra-arterial DBP measurements 10 to 15 mm Hg below indirect BP cuff diastolic measurements. None of the definitions specifically addresses the SBP. If a patient is suspected of having pseudohypertension, confirmation by intra-arterial pressure measurement may be considered, with decision for treatment goals based on the intra-arterial findings.

Isolated Systolic Hypertension Arteriosclerosis, characterized by remodeling and stiffening of large elastic arteries, is the most significant manifestation of vascular aging.²⁶ The increased stiffening is believed to originate from a gradual mechanical senescence of the elastic network, alterations in cross-linking of extracellular matrix components, fibrosis, and calcification of elastic fibers. Stiffening of large arteries reduces their capacitance and accelerates pulse wave velocity, thus contributing to a widening of pulse pressure and to the increased prevalence of isolated systolic hypertension (ISH) with age. Perhaps as a consequence,

the increase in SBP continues throughout life, in contrast to DBP, which increases until the age of 50 years and decreases later in life (Fig. 32.15). Diastolic hypertension is more common before the age of 50 years, either alone or in combination with elevated SBP. After the age of 50 years, SBP is more important than DBP.

ISH is defined as SBP of 140 mm Hg or higher and DBP of 90 mm Hg or lower. The prevalence of ISH increases with age and affects most individuals older than 60 years. In the Framingham study, elevations in SBP determined a greater risk of both heart attacks and strokes compared with elevations of DBP. Indeed, JNC 7 assigned SBP a higher level of importance than DBP.¹² Several clinical trials have clearly demonstrated that treatment of ISH reduces the cardiovascular event rate.²⁷ Nevertheless, controversy exists as to the choice of antihypertensive agents. Elderly hypertensive patients should be treated aggressively to the same target BPs identified for younger patients. However, it is appropriate to initiate treatment with lower doses of antihypertensive agents and to bring the pressure down more slowly, monitoring for orthostatic hypotension, impaired cognition, and electrolyte abnormalities.

Resistant Hypertension Resistant hypertension is defined as BP that is not at treatment goal despite optimal doses of three antihypertensive drugs, including a diuretic. Although it is not well quantified, some clinical trials suggest that resistant hypertension may occur in 30% of hypertensive subjects. Older age and obesity are strong risk factors. Secondary hypertension is more common in resistant hypertension, with primary aldosteronism reported in 18% to 23% of patients.²⁸

Accelerated Hypertension/Hypertensive Urgencies and Emergencies Accelerated hypertension is severe diastolic hypertension (usually >120 mm Hg) in the presence of grade III retinopathy (arteriolosclerotic changes of arteriolar narrowing and nicking plus hypertensive changes of flame-shaped hemorrhages and soft exudates).²⁹ In the past, “malignant” hypertension referred to severe diastolic hypertension and grade IV retinopathy (grade III plus papilledema). Because the prognosis for untreated severe hypertension with grade III or IV retinopathy is so poor, there is little clinical rationale for using the two terms separately. More recently, accelerated hypertension with hypertensive retinopathy is defined as a hypertensive urgency if treatment is required to decrease BP within hours, whereas hypertensive emergencies are clinical conditions in which severe hypertension must be lowered within minutes. Emergencies include acute dissection of the aorta, acute left ventricular failure, intracerebral hemorrhage, and crises caused by pheochromocytoma, drug abuse, and eclampsia (see Chapter 36).

Hypertension in Children Hypertension in children is defined by average SBP or DBP at or above the 95th percentile for gender and age, measured on at least three occasions. The reported causes of hypertension in children vary. Most prepubertal hypertension is thought to have renal causes, although some children may have BP levels above the 95th percentile because of an earlier growth spurt and large size. In postpubertal children, mild hypertension is likely to be primary hypertension, whereas more severe hypertension is usually of renal cause. Primary aldosteronism and thyroid disease seem rare.

Hypertension in Pregnancy Hypertension may occur in more than 5% of all pregnancies and in approximately 5% of women

Figure 32.15 Changes in systolic and diastolic blood pressure with age. Systolic blood pressure and diastolic blood pressure by age and race or ethnicity for men and women older than 18 years in the U.S. population. Data from NHANES III, 1988 to 1991. (From reference 30.)

taking oral contraceptives. Definitions and implications of hypertension in pregnancy are discussed in Chapters 42 and 43.

Classification by Cause of Hypertension

Although a large number of causes are recognized for hypertension, the etiology in 90% to 95% of patients with hypertension is unknown. These patients are considered to have primary (or essential) hypertension (see Chapter 33). Figure 32.16 shows the more common causes of secondary hypertension. These include renal parenchymal disease (2% to 6% of all hypertensives), renovascular hypertension (1% to 4%), and all endocrine hypertension (traditionally thought to be 1%, including primary aldosteronism, pheochromocytoma, Cushing's syndrome, and others). More recent studies have shown an increasing prevalence of primary aldosteronism, ranging from 2% to 13% in stage 1 to stage 3 hypertension. Other causes include coarctation of the aorta (0.1% to 1.0%) and obstructive sleep apnea and obesity. An often overlooked cause of hypertension is drug induced (1%), including oral contraceptives, decongestants or sympathomimetic agents, and nonsteroidal anti-inflammatory drugs (NSAIDs).

EVALUATION OF HYPERTENSION

Proper Measurement of Blood Pressure

Arterial BP is usually measured in the brachial artery by use of the cuff-based sphygmomanometer, in which the arterial pressure is recorded by detecting sounds that are generated (auscultatory method) or by recording vascular pulsations (oscillometric method) after decompression of a compressed artery. Guidelines for BP measurement are given in Figure 32.17. Unfortunately, if it is not properly used, the method can be unreliable and inaccurate. The most common reason for inaccuracy is an

inappropriate cuff size as the accuracy of these measurements is influenced by the size of the inflatable bladder relative to the girth of the compressed limb. To provide uniform compression of the underlying artery, the length of the bladder should be at least 80% of the upper arm circumference, and the width of the bladder should be at least 40% of the upper arm circumference. A simple bedside maneuver to check the appropriateness of the cuff size consists of aligning the cuff so that its long axis is parallel to the long axis of the arm. The bladder width should then be sufficient to encircle half of the upper arm circumference. If the bladder width encompasses less than half of the upper arm, a larger cuff must be selected. No change in cuff size is necessary if the cuff width encircles more than half the upper arm because large cuffs on thin limbs do not produce considerable errors in the BP measurement. For purists, accepted bladder dimensions for varying arm sizes are given in Figure 32.18. Another potential error relates to the auscultatory method, which relies on the ability to hear the Korotkoff sounds. The human ear has a sound threshold of about 16 Hz. The Korotkoff sounds occur at slightly above this level (25 to 50 Hz). Thus, the human ear is almost deaf to the sounds it must hear to measure BP. The bell-shaped stethoscope head should be used to measure BP. Interestingly, many physicians and most nurses are not equipped with a bell-shaped stethoscope head.

The oscillometric method is based on the principle of plethysmography to detect pulsatile pressure changes in a nearby artery. When an arm cuff is inflated, pulsatile pressure changes in an underlying artery produce periodic pressure changes in the inflated cuff. The oscillometric method thus measures periodic pressure changes, oscillations, in an inflated cuff as an indirect measure of pulsatile pressure in an underlying artery.

There are three types of sphygmomanometer in use worldwide. Because of environmental concerns, the standard mercury manometer has been abandoned in some areas.³¹ The second type

Common Causes of Secondary Hypertension	
Condition/Disorder	Diseases: Comments
Renal disorders	Renal parenchymal disease: acute and chronic glomerular diseases, chronic tubulointerstitial disease, PKD, obstructive uropathy Renovascular disease: renal artery stenosis caused by atherosclerosis or fibromuscular dysplasia; arteritis; extrinsic compression of the renal artery Other renal causes: renin-producing tumors, renal sodium retention (Liddle syndrome)
Endocrine disorders	Adrenocortical disorders: primary aldosteronism, congenital adrenal hyperplasia, Cushing's syndrome Adrenomedullary tumors: pheochromocytoma (also extra-adrenal chromaffin tumor) Thyroid disease: hyperthyroidism, hypothyroidism Hyperparathyroidism: hypercalcemia Acromegaly Carcinoid tumors
Exogenous medications and drugs	Oral contraceptives, sympathomimetics, glucocorticoids, mineralocorticoids, NSAIDs, calcineurin inhibitors, tyramine-containing foods and monoamine oxidase inhibitors, EPO, ergot alkaloids, amphetamines, herbal remedies, licorice (mimics primary aldosteronism), ethanol, cocaine and other illicit drugs, abrupt withdrawal of clonidine
Pregnancy	Preeclampsia and eclampsia
Coarctation of the aorta	
Neurologic disorders	Sleep apnea Increased intracranial pressure: brain tumors Affective disorders Spinal cord injury: quadriplegia, paraplegia, Guillain-Barré syndrome Baroreflex dysregulation
Psychosocial factors	
Intravascular volume overload	
Systolic hypertension	Loss of elasticity of aorta and great vessels Hyperdynamic cardiac output: hyperthyroidism, aortic insufficiency, anemia, arteriovenous fistula, beri-beri, Paget's disease of the bone
Obesity	White adipose tissue has endocrine function: leptins; adiponectin; cytokines; chemokines; Ang II; other adipokines

Figure 32.16 Common causes of secondary hypertension. Ang II, angiotensin II; EPO, erythropoietin; NSAIDs, nonsteroidal antiinflammatory drugs; PKD, polycystic kidney disease.

in wide use is the aneroid manometer. There are also numerous semiautomatic oscillometric electronic recording manometers. The manufacturers must ensure accuracy, and in many countries, the local hypertension societies have arranged for certification of these devices. The technical capabilities of the devices have increased greatly. Physicians must be aware that many patients purchase devices and measure their own BP. These devices should be inspected and checked by the physician.

Variability of Blood Pressure

Wake-Sleep Cycle and Office Versus Home Blood Pressure

BP varies considerably in individual subjects and may vary significantly throughout the day. This variation causes considerable difficulties in identifying individuals who are hypertensive, especially in terms of the preceding classification schemes. The differing BP values are due to both biologic variation (variations of pressures within a given individual) and variation in the measurement itself. Errors in measurement can be minimized by attention to the proper technique for recording BP, as noted previously. Biologic variation is addressed by repeated BP measurement at a given visit (at least two pressures taken at least 30 seconds apart or additional BP measurements if there is a difference of 5 mm Hg between repeated measures). In addition, in most patients with milder forms of hypertension, repeated

measurements during different clinic visits over time are recommended to approach the true BP.

Readings of BP at home, and outside the clinic or office setting, are recommended to assess the severity and frequency of hypertension and BP control during treatment. The instruments used at home must be checked against a standard on a regular basis, and the techniques for correct BP measurement must be taught to the patient. This includes having the brachial artery at the level of the heart when BP is measured. Levels measured at home are generally lower than those measured in the clinic or office. Patients should be discouraged from very frequent home BP measurement and from frequent adjustment of medications, which may result in unnecessary emergency department visits and hospital admissions for symptomatic hypotension or uncontrolled hypertension. It is worthwhile to ask the patient to keep a daily calendar and to measure BP under controlled conditions two or three times daily, for instance, while sitting quietly in the mornings, afternoons, and evenings. If three fourths of the measurements achieve goal or better, office control is generally also achieved.

Biologic variation during the day is related to physical and mental activity and emotional factors. There is also diurnal variation, with a decrease in BP during sleep (averaging 20%) secondary to a decrease in sympathetic activity; similar reductions in BP occur after hospital admission and bed rest. The normal diurnal pattern includes an increase in BP before awakening that

Guidelines for Measurement of Blood Pressure	
Factors	Important Features
Patient factors	<p>Caffeine should not be taken for up to 1 hour before the blood pressure measurement.</p> <p>Cigarettes should not be smoked for at least 15 minutes prior to the blood pressure reading.</p> <p>The standard measurement should be made with the patient seated comfortably, arm supported, and the cuff must be at the level of the heart; the arm should be bared.</p> <p>On an initial examination, blood pressure should also be checked in the supine position after 5 minutes of rest, in the standing position after 2 minutes, and in both arms in patients who are diabetic, older than 65 years, or receiving antihypertensive therapy. Use the higher value if the arms have differing blood pressures.</p> <p>If sequential pressures are taken in the same position, at least 30 seconds must elapse between blood pressure readings.</p> <p>In patients younger than 30 years, check blood pressure in one leg.</p> <p>To establish a diagnosis of hypertension, obtain blood pressure readings on three different occasions, at least 1 week apart.</p>
Equipment	<p>The length of the bladder with the cuff should encircle at least 80% of the arm.</p> <p>The width of the cuff should be equal to two thirds of the distance from the antecubital space to the axilla and be 40% of the arm circumference. The best cuff for most adults is the 15-cm-wide cuff with a bladder of 33–35 cm in length. The distal edge of the cuff should be 2.5 cm above the antecubital fossa. For leg BP, thigh cuff length should encircle 80% of the thigh, and width should be 40% of the thigh circumference. For leg BP, the patient should be prone and popliteal artery sounds measured by auscultation. For automated equipment, the sensor should be over the brachial (or radial or popliteal) artery.</p> <p>In extremely obese patients, blood pressure may be more accurate when measured in the forearm, palpating and auscultating the radial artery.</p> <p>For infants, ultrasound equipment may need to be used. The bell of the stethoscope is preferred.</p>
Technique	<p>The initial systolic blood pressure should be checked by palpating the disappearance of the radial or brachial pulse prior to auscultation and the cuff then deflated.</p> <p>The second blood pressure check requires cuff inflation 20–30 mm Hg above the palpable systolic level.</p> <p>Deflate the cuff at a rate of 2–4 mm Hg per second.</p> <p>Record the Korotkoff sound I (appearance of sound) as the systolic pressure and record the Korotkoff sound V (the last sound before complete disappearance of sound) as the more reproducible diastolic pressure. If the sounds do not disappear, record the muffled sound (phase IV) as the diastolic.</p> <p>The sounds may be augmented by having the patient raise the arm and by opening and closing the hand 10 times before inflating the pressure.</p> <p>Do not stop between systolic and diastolic readings; deflate the cuff, wait at least 30 seconds, and then reinflate. On each occasion, record at least two readings. If the readings vary by more than 5 mm Hg, take additional readings until two are within 5 mm Hg.</p> <p>In children, the same standards apply for cuff size; Korotkoff sound V should be used. If the child is uncooperative, the systolic blood pressure may be determined by palpation.</p>

Figure 32.17 Guidelines for measurement of blood pressure.

Accepted Bladder Dimensions for Varying Arm Sizes			
Patient	Arm Circumference Range at Midpoint (cm)	Bladder Width (cm)	Bladder Length (cm)
Newborn	6	3	6
Infant*	6–15	5	15
Child*	16–21	8	21
Small adult	22–26	10	24
Adult	27–34	13	30
Large adult	35–44	16	38
Adult thigh	45–52	20	42

Figure 32.18 Accepted bladder dimensions for varying arm sizes.

*To approximate a bladder width to arm circumference ratio of 0.4 more closely in children, additional cuffs are available. There is some overlap in the recommended ranges for arm circumference to limit the number of cuffs. It is suggested that the larger cuff be used if it is available. (From reference 32.)

has been associated with increased incidence of myocardial infarction, stroke, and sudden death in the first few hours after awakening. Those with the usual pattern of BP decrease during sleep are known as nocturnal “dippers.” Those whose BP does not fall during sleep are called “nondippers.” The failure to decrease BP during sleep has been associated with increased incidence of left ventricular hypertrophy and raises the possibility of secondary hypertension.

Ambulatory Blood Pressure

Because of the variability in BP that occurs throughout the day, home BP and ambulatory BP monitoring are used to define BP more clearly. Home BP monitoring is advised for all patients and may help identify white coat hypertension and borderline hypertension and may also help monitor response to therapy, including identification of hypotension as well as hypertension. The instructions to each patient must be individualized, but home BP monitoring may be advised two or three times per day while the patient is awake. These BP values must be self-recorded and reviewed. The prognostic value of ambulatory and home BP compared with office BP in the general population was recently reported from the Pressioni Arteriose Monitorate e Loro Associazioni (PAMELA) study.³³ A total of 2051 persons were observed for 10 years; risk of death increased more with a given

Figure 32.19 Increase in 11-year risk of cardiovascular (CV) mortality for 10 mm Hg increase in office, home, and ambulatory blood pressure (BP) at various initial BP values. (Reprinted with permission from reference 33.)

increase in home or ambulatory BP than in office BP. The overall ability to predict death, however, was not greater for home and ambulatory than for office BP, although it was somewhat increased by the combination of office and outside-of-office values. SBP was almost invariably superior to DBP, and night BP was superior to day BP (Fig. 32.19).

Ambulatory BP monitoring is recommended for certain indications beyond the information available from home BP recording (Fig. 32.20). Ambulatory BP monitoring uses a noninvasive system. The BP is determined by auscultation with use of either oscillometry, which measures variations in pressure within the cuff, or a microphone placed under the cuff and over the brachial artery. The ambulatory BP device can be programmed to record at frequent intervals during the daytime (e.g., every 10 minutes) and less frequently at night during sleep (e.g., every 30 minutes). The ambulatory BP equipment might not provide accurate readings in patients with large upper arms due to obesity or increased musculature, and the equipment may be inaccurate during vigorous activity. The equipment generally records BP during a 24-hour period. Although most patients adjust to the repetitive measurements throughout the day, some patients may have a startle response with each BP recording. Most patients are able to sleep, although some have their sleep disturbed by the BP recording, and therefore determination of nocturnal fall in BP is inaccurate. Indications for ambulatory BP determinations are shown in Figure 32.21.³⁴

There are disadvantages to use of the ambulatory BP equipment. Trained personnel must place the monitoring equipment. Calibration of ambulatory BP equipment with a mercury manometer must be recorded at the beginning and end of the ambulatory BP session. Three to six readings must be taken at each time, and the SBP and DBP measurements must both agree within 5 mm Hg. The end calibration is critical to ensure proper functioning of the ambulatory BP monitor throughout the 24-hour period. The cuff inflation may interfere with activities, work, or sleep. The cuff may cause discomfort or skin irritation, or it may

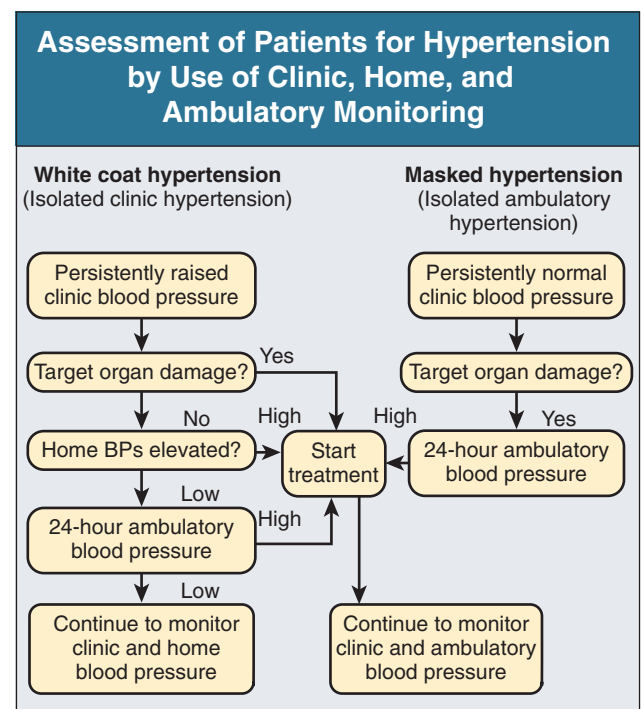

Figure 32.20 Guidelines for assessment of patients by use of clinic, home, and ambulatory monitoring of blood pressure.

malfunction and fail to deflate, causing pain and interruption of recording. The data correlating ambulatory BP with target organ disease are limited. Standards for assessment of data and their use in decisions for therapy are limited. In addition, equipment is expensive and its use is limited by lack of reimbursement by health insurance systems in a number of countries, including the United States and some European countries.

Risk Factors for Hypertension

A number of factors are known to be associated with an increased risk of primary hypertension.³⁵ These are discussed in detail in Chapter 33 (see Fig. 33.8).

Evaluation for Primary Versus Secondary Hypertension

The medical history, the physical examination, and a limited number of laboratory tests provide critical information in deciding which individuals require further evaluation for secondary hypertension and target organ disease (Figs. 32.22 and 32.23). All hypertensive persons should be assessed for cardiovascular risk factors, including total cholesterol, HDL and LDL cholesterol, fasting triglycerides, renal function, and proteinuria (according to the Kidney Disease Outcomes Quality Initiative

classification), and for the presence of diabetes mellitus or the metabolic syndrome.

Some authorities advocate assessment of patients with primary hypertension in terms of their plasma renin activity (renin profiling).³⁶ The notion is to treat patients with low plasma renin activity with drugs aimed at volume reduction and those with higher values with drugs aimed at peripheral vascular resistance. Although a 24-hour urine collection for sodium excretion is helpful information, the collection is not mandatory, nor must all medication be discontinued before a renin measurement. According to renin profiling, patients with plasma renin activity below 0.65 ng/ml/h are more likely to have volume-related hypertension, whereas those with values above 0.65 ng/ml/h have more predominant vasoconstriction. Systematic drug rotation studies have shown that the rank order of response to different drugs indeed varies substantially among patients.³⁷ In support of renin profiling, two broad patterns of response emerged. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and β -blockers were useful primarily in hypertensive patients with higher renin values. These patients are generally younger Caucasians. Calcium channel blockers and diuretics were more useful in low-renin hypertension, which is commonly observed in Afro-Caribbeans, African Americans, and older Caucasians.

If the history, physical examination, or screening laboratory studies suggest secondary hypertension, additional studies are warranted. If renal parenchymal disease is suspected, quantitative studies to assess GFR and urinary protein excretion should be performed. Renal ultrasound is useful to evaluate renal size and echogenicity (to help assess chronicity) and to evaluate for obstructive uropathy. Renal artery stenosis should be suspected by the presence of severe hypertension with abnormal renal function or with asymmetric renal size. If primary aldosteronism is suspected because of hypokalemia, the ratio of plasma aldosterone to plasma renin activity may be useful. If the ratio is above 25 to 30 and plasma aldosterone concentration is more than 20 ng/dl, the diagnosis should be pursued further. The extended results of patients undergoing operation have been published.³⁸ Resolution of hypertension after adrenalectomy for primary aldosteronism was independently associated with a lack of family history of hypertension and preoperative use of two or fewer antihypertensive agents. Further evaluation for other forms of secondary hypertension is listed in Figure 32.23.

Indications for Ambulatory Blood Pressure Measurement
White coat hypertension
Evaluation of apparent drug resistance
Hypotensive symptoms
Autonomic dysfunction
Episodic hypertension
Evaluation of nocturnal decreases in blood pressure as a prognostic factor for target organ disease (left ventricular hypertrophy, ischemic optic neuropathy)
Evaluation of blood pressure changes in patients with paroxysmal nocturnal dyspnea and nocturnal angina
Carotid sinus syncope
Pacemaker syndromes
Safety of withdrawing antihypertensive medication
Assess 24-hour blood pressure control on once-daily medication
Borderline hypertension with target organ damage
Evaluation of antihypertensive drug therapy in clinical trials

Figure 32.21 Indications for ambulatory blood pressure measurement.

Evaluation for Primary Versus Secondary Hypertension			
Classification	Medical History	Physical Examination	Laboratory Studies
General information and evaluation of target organs	Duration and course of hypertension Prior workup and treatment Diet/lifestyle: salt intake, tobacco, caffeine	Evaluation of volume status, optic fundi, heart, lungs, peripheral vessels, and nervous system	Complete blood count, fasting glucose, lipid profile (includes HDL, LDL, cholesterol, triglyceride), uric acid Consider echocardiogram
Primary (essential or idiopathic) or secondary?	Family history: hypertension, cardiovascular and renal diseases Symptoms of target organ disease (related to eyes, central nervous system, cardiorespiratory, and peripheral vascular)	See Figure 32.23 for signs suggestive of secondary hypertension	See Figure 32.23 for additional laboratory studies to rule out secondary hypertension

Figure 32.22 Evaluation for primary versus secondary hypertension. HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Evaluation of Secondary Hypertension			
Target Organ/System	Medical History	Physical Examination	Laboratory Studies
Kidney Renal parenchymal	History of renal disease (including glomerulonephritis, nephrotic syndrome, calculi, urinary tract infection) Symptoms include nocturia, frequency, dysuria, hesitancy, urgency, incomplete emptying, dribbling, hematuria, pyuria, flank pain	Tenderness in costovertebral angles; palpable kidneys	BUN, serum creatinine; urinalysis, urine culture if indicated; 24-h urine for protein and creatinine clearance if indicated; consider microalbuminuria measurement, or random urine protein to creatinine ratio
Renovascular hypertension		Epigastric bruit; other vascular bruits	Renal ultrasonography with duplex Doppler flow study; consider angiography or magnetic resonance angiography
Endocrine Primary aldosteronism	Muscle weakness, cramps		Serum potassium: consider serum aldosterone to plasma renin activity ratio; 24-h urine aldosterone, Na, K, creatinine
Cushing's syndrome	Weight gain, cosmetic changes	Body habitus: body fat, striae	Morning serum cortisol after dexamethasone suppression
Pheochromocytoma	Headaches; vasomotor symptoms, (inappropriate sweating, pallor); cardiac symptoms (awareness, tachycardia, palpitations)	Paroxysmal or intermittent hypertension (50% of patients)	Single voided urine for metanephrine and creatinine; consider 24-h urine for VMA, metanephrines; and catecholamines; if positive, proceed with magnetic resonance imaging or thin-section computed tomography of the adrenals
Carcinoid	Flushing		24-h urine 5-hydroxyindoleacetic acid excretion
Hyperthyroidism	Weight loss, tachycardia, palpitations, sweating, heat intolerance	Palpable thyroid	Total and free thyroxine
Hypothyroidism	Weight gain, dry skin, cold intolerance, hair loss		Thyroid-stimulating hormone, total and free thyroxine
Hyperparathyroidism	Nausea, vomiting, bone pain, nephrolithiasis		Serum calcium, intact parathyroid hormone
Acromegaly	Change in size of head, hands, or feet (adult)	Appearance	GH level (see Figure 39-10)
Medication	Review of prescribed and over-the-counter medications (especially oral contraceptives, NSAIDs, sympathomimetic agents [cold and allergy drugs], illicit or recreational drugs, including alcohol, herbal remedies)		
Coarctation of the aorta	Onset or detection of hypertension in childhood or adolescence	Simultaneous palpation of radial and femoral arteries to detect pulse lag in femorals; leg blood pressure	Chest radiograph for heart size, configuration of aorta, rib notching; consider aortography
Neurologic disorders Sleep apnea	Obesity; weight gain; daytime somnolence; snoring, poor sleep habits (frequent awakening, not rested on arising); early morning headache	Obesity; narrowed airway in hypopharynx; redundant pharyngeal tissue	Formal sleep study (polysomnography)
Increased intracranial pressure Affective disorders [†] Spinal cord injury [†]	Headache; neurologic symptoms	Papilledema	↑Cerebrospinal fluid pressure
Psychosocial factors	Family and support structure, occupation, education, stressors		
Volume overload	Excess salt and water intake (may be iatrogenic with excess parenteral fluid)	Increased jugular venous distention, Chest radiograph pulmonary rales, presacral and peripheral edema, hepatomegaly	
Isolated systolic hypertension		Pseudohypertension (positive Osler's maneuver); cardiac and vascular examination (evaluate for aortic insufficiency, arteriovenous fistula)	

Figure 32.23 History, physical examination, and initial laboratory evaluation for secondary hypertension. A more detailed discussion is provided in other relevant chapters. Pregnancy-associated hypertension is discussed in Chapters 42 and 43. [†]Medical history, physical examination and laboratory tests are either obvious or beyond the scope of the discussion. BUN, blood urea nitrogen; NSAIDs, nonsteroidal antiinflammatory drugs.

Primary Hypertension

Richard J. Johnson, Bernardo Rodriguez-Iturbe, George L. Bakris

DEFINITION

Primary (also known as essential) hypertension is defined as a blood pressure (BP) above 140/90 mm Hg without an identifiable cause. Several readings on different occasions and times are necessary to document that the BP is elevated because of substantial variability in BP. This variability in BP results from a circadian rhythm that generates the most significant increase in BP in early morning hours (6:00 to 10:00). BP falls at bedtime with recumbency or sleep, secondary to a decrease in sympathetic nervous system tone and reduced activity of other neuroendocrine systems. There are also minute-to-minute variations in BP (Fig. 33.1). Transient elevations in BP, reaching 150 mm Hg systolic, occur in the majority of normotensive subjects on any given day.¹ However, BP that is repeatedly 140/90 mm Hg or greater is considered elevated. Details on the method and interpretation of BP measurements, including the use of ambulatory BP monitoring, can be found in Chapter 32.

Hypertension is classified according to severity (Fig. 33.2).² Stages in hypertension have been adapted by both the Joint National Committee (JNC 7) and the European Society of Hypertension and European Society of Cardiology (ESH/ESC) guidelines to allow a prognosis to be associated with different levels of BP elevation. The prognosis has been adapted from epidemiologic studies that demonstrate a linear relationship between the risk of cardiovascular events and sustained elevations of arterial pressure.

If only the systolic BP is elevated (systolic BP >140 mm Hg and diastolic BP <90 mm Hg), it is called isolated systolic hypertension. The former terms borderline hypertension and high-normal hypertension (defined as BP of 130 to 139/85 to 89 mm Hg) are now classified as prehypertension (defined as BP \geq 120 to 139/80 to 89 mm Hg). White coat hypertension is an elevation of more than 20 mm Hg in systolic pressure noted only in the physician's office above that seen at home or in another setting. In contrast, masked hypertension is BP that is normal in the office but elevated by more than 20 mm Hg when it is measured by ambulatory BP monitoring.

Other terms used to describe specific clinical presentations include hypertensive emergencies, which are associated with acute end-organ damage requiring immediate treatment, usually in the intensive care unit, and hypertensive urgencies, which need correction in hours or a few days (see Chapter 36). In hypertensive crises, the reduction of BP will halt, prevent, or reverse falling glomerular filtration rate (GFR). These terms have replaced malignant hypertension and accelerated hypertension. Resistant hypertension is defined as hypertension that remains above 140/90 mm Hg despite use of three maximally dosed antihypertensive medications of different classes.

ETIOLOGY AND PATHOGENESIS

The kidney has a key role in the pathogenesis of hypertension. Guyton proposed that the kidney in subjects with hypertension has a physiologic defect in sodium excretion. Whereas an increase in sodium intake is associated with a rise in pressure and prompt excretion of the salt load in most subjects, this pressure-natriuresis relationship is abnormal in the hypertensive subject³ (Fig. 33.3). In some hypertensive subjects, especially those younger than 40 years, the response to a salt load is similar to that of normal subjects but is just shifted rightward such that higher pressures are required for a specific salt load (salt-resistant hypertension). In contrast, some hypertensive subjects, and especially older subjects and African Americans, have both a rightward shift and a change in the slope such that BP increases more for the same sodium load (i.e., salt-sensitive hypertension). Additional evidence in support of a renal defect in sodium handling comes from the observation that kidney transplantation can transfer the susceptibility for hypertension in response to salt in various rat strains. Epidemiologic studies have also documented that dietary sodium content correlates with the prevalence of hypertension in various populations, and intervention studies with salt restriction or loading have shown that the BP response in many hypertensive patients is salt sensitive. The basis for this renal defect in hypertension remains controversial, but three major hypotheses have been proposed.

Genetic (Polygene) Hypothesis

Pickering and later Lifton proposed that hypertension results from the expression of multiple genetic polymorphisms (polygene hypothesis) that favor sodium retention by the kidney in a westernized society in which there is often excessive intake (>10 g/day) of salt. The observation that numerous monogenic forms of both hypertension and hypotension are mediated by specific mutations involving sodium transport, especially involving the epithelial sodium channel (see Chapter 47), supports this hypothesis (Fig. 33.4).⁴ Indeed, more than 20 genes have been identified in which mutations or polymorphisms can strongly influence BP.⁴ Many of these involve sodium transport in the distal tubule or the collecting duct. Interestingly, some heterozygous mutations (such as the Na-K-2Cl cotransporter *SLC12A1* or the inward rectifier K⁺ channel *KCNJ11*) that are carrier states for Gitelman's syndrome and the heterozygous mutation of the Na-Cl cotransporter *SLC12A3* that is a carrier state for Bartter syndrome actually confer protection from hypertension.⁵ Whereas genetic polymorphisms clearly have an important influence on BP, many studies suggest that genetic mechanisms can account for only 20% to 30% of cases of primary hypertension,

Figure 33.1 Blood pressure variability in a normotensive individual. In most normal individuals, systolic blood pressure reaches 150 mm Hg at least once per day. (Reprinted with permission from reference 1.)

Classification of Blood Pressure			
BP Classification	Systolic BP (mmHg)		Diastolic BP (mmHg)
Normal	<120	and	<80
Prehypertension	120–139	or	80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	≥160	or	≥100

Figure 33.2 Classification of blood pressure. Shown is the BP classification according to the seventh report of the Joint National Committee on Prevention, Detection, and Treatment of High Blood Pressure: the JNC 7 report. (From reference 2.)

Figure 33.3 A physiologic defect in sodium excretion in primary hypertension. Evidence suggests that in patients with primary hypertension, a higher blood pressure is required to excrete an individual sodium load. In salt-resistant hypertension, the pressure-natriuresis curve has a rightward but parallel shift; with salt-sensitive hypertension, it is a shift to the right as well as a change in slope. (Modified from reference 4.)

Monogenic Diseases Associated with Alterations in Blood Pressure					
Condition	Gene	Inheritance	Site	Manifestations	
Glucocorticoid-remediable aldosteronism (GRA)	Chimeric ACTH-responsive promoter with aldosterone synthase	AD	Collecting duct	Hypertension, metabolic alkalosis	
Mendelian hypertension exacerbated by pregnancy	Gain-of-function of mineralocorticoid receptor (MR)	AD	Collecting duct	Hypertension, worsened by pregnancy (progesterone)	
Liddle syndrome	Gain-of-function of β or γ subunit of epithelial sodium channel (ENaC)	AD	Collecting duct	Hypertension, metabolic alkalosis	
Pseudohypoaldosteronism type 1 (PHA1)	ENaC loss of function MR loss of function	AR AD	Collecting duct	Neonatal hypotension, acidosis, salt wasting	
Gitelman's syndrome	Na-Cl cotransporter (NCC) Loss of function	AR	Distal convoluted tubule (DCT)	Low BP, salt wasting, metabolic alkalosis	
Bartter syndrome	4 gene mutations: Na-K-2Cl, K channel, C1 channel, Barttin	AD or AR	Thick ascending limb	Low BP, salt wasting, metabolic alkalosis	
Metabolic syndrome	Mitochondrial tRNA	Maternal	?	Hypertension, hypercholesterolemia, hypomagnesemia	
Pseudohypoaldosteronism type 2 (PHA2) or Gordon's syndrome	WNK1 and WNK4 serine threonine kinases	AD	DCT and Collecting duct	Hypertension, \uparrow K, metabolic acidosis

indicating that other mechanisms are also likely to be operative.

Congenital (The Low Nephron Number) Hypothesis

In 1989, Barker reported an increased risk for hypertension, obesity, and diabetes in subjects with low birth weights.⁶ Mothers of low-birth-weight infants frequently have hypertension, obesity, preeclampsia, or malnutrition, and these maternal factors are also associated with an increased risk for hypertension in the progeny. Brenner and colleagues⁷ independently postulated that hypertension might be predisposed by being born with kidneys with a lower nephron number, which commonly occurs in low-birth-weight infants. Consistent with this hypothesis, experimental studies have demonstrated that maternal malnutrition predisposes to small babies, a low nephron number, and the future predisposition for hypertension. Furthermore, a study reported that Caucasians with primary hypertension have nearly 50% fewer nephrons than do age- and sex-matched controls.⁸ However, more recent studies in the African American population could not confirm the relationship between low nephron number and hypertension. In addition, low birth weight cannot be the primary risk factor. For example, one study found that although low-birth-weight infants have a 25% risk for development of hypertension as adults, high-birth-weight infants have a 20% risk.⁹ Thus, other mechanisms are also likely contributory in the pathogenesis of hypertension.

Acquired Renal Injury Hypothesis

Primary hypertension is commonly associated with renal arteriosclerosis and hyalinosis with variable degrees of glomerulosclerosis and ischemic tubular injury. Whereas renal function is often normal or only slightly depressed, renal vascular resistance is high due to intense vasoconstriction of the afferent arteriole. It is likely that overt structural changes are the consequence of hypertension; yet experimental induction of microvascular disease and renal inflammation in normal rats also results in the development of salt-sensitive hypertension.

Salt-sensitive hypertension can be induced by a variety of means that usually involve renal vasoconstriction (Fig. 33.5). Renal microvascular injury leads to oxidative stress, resulting in an influx of macrophages and T cells, activation of the local renin-angiotensin system (RAS), and a decrease in local nitric oxide. Some studies suggest that the local T cells may be reacting with *de novo* expressed antigens, such as heat shock protein 70, to cause the hypertensive response. These data are consistent with accumulating evidence that T cells may have a role in the pathogenesis of hypertension. Indeed, blocking of T cells and macrophage accumulation in the kidney with mycophenolate mofetil (MMF) can prevent hypertension in various experimental models of salt-sensitive hypertension. Interestingly, rats born with low nephron number also develop renal microvascular disease and intrarenal T-cell accumulation, and administration of MMF also reduces BP in these animals. MMF has also been reported to lower BP in humans with psoriasis and primary hypertension.

How Does Renal Injury Lead to Sodium Retention?

Renal tubulointerstitial inflammation, local oxidative stress with inactivation of nitric oxide, and local angiotensin II (Ang II) activity maintain intrarenal vasoconstriction and sodium retention. Afferent arteriole remodeling results from the

Mechanisms that can Induce Salt-Sensitive Hypertension in Experimental Animals

Angiotensin II infusion
Inhibition of nitric oxide synthesis (treatment with L-NAME)
Catecholamine infusion
Diet-induced hypokalemia
Hyperuricemia induced by uricase inhibition
Reduced nephron number via maternal malnutrition
Induction of nephrotic syndrome with use of bovine serum albumin
Page kidney
Lead-induced hypertension
Cyclosporine nephropathy
Genetic models of hypertension (Dahl salt-sensitive rat, spontaneously hypertensive rat)

Figure 33.5 Mechanisms that can induce salt-sensitive hypertension in experimental animals. All experimental models involve the development of renal microvascular injury and interstitial inflammation.

increased BP as well as from a direct stimulation of smooth muscle cell proliferation by Ang II and other mediators. Whereas the renal arteriolar disease is mild, a given sodium gain is met with a rise in systemic and renal perfusion pressures, and the pressure-natriuresis relationship maintains the same slope as in the normal response, resulting in a salt-resistant form of hypertension. As progressive renal arteriosclerosis develops, there is uneven blood perfusion of the kidney, with underperfused areas distal to regions with severe arteriolar disease and overperfused areas distal to areas with preserved arteriolar structure. The consequence of this condition is renal ischemia with a right shift of the pressure-natriuresis curve with a change of the slope, characteristic of salt-sensitive hypertension (Fig. 33.6).¹⁰

What Pathogenic Mechanisms Are Driving the Current Epidemic of Hypertension?

As discussed later (see Epidemiology), there has been a marked rise in the prevalence of hypertension in the last century. There is evidence that the marked rise in hypertension corresponds with the introduction of Western diet and lifestyle and with the dramatic increase in obesity. Obesity may cause hypertension through multiple mechanisms, including subtle renal injury, the effects of hyperleptinemia or hyperinsulinemia, the coexistence of endothelial dysfunction, and the activation of the sympathetic nervous system (SNS).¹¹ However, a recent hypothesis suggests that the rapid increase in sugar intake (and in particular fructose) may have a direct role in driving the obesity and hypertension epidemic.¹² Fructose is unique among sugars in being rapidly phosphorylated within the cell, resulting in local adenosine triphosphate (ATP) depletion and uric acid generation. In turn, uric acid has been shown to induce endothelial dysfunction, to activate the local and systemic RAS, to stimulate aldosterone, and possibly to activate the SNS. Experimentally induced hyperuricemia also causes hypertension with afferent arteriolar disease and tubulointerstitial inflammation similar to that observed with other vasoconstrictive agents.

Studies in humans and experimental animals suggest that fructose can raise BP by a uric acid-dependent mechanism. Uric acid levels have risen in the last century in parallel with increased

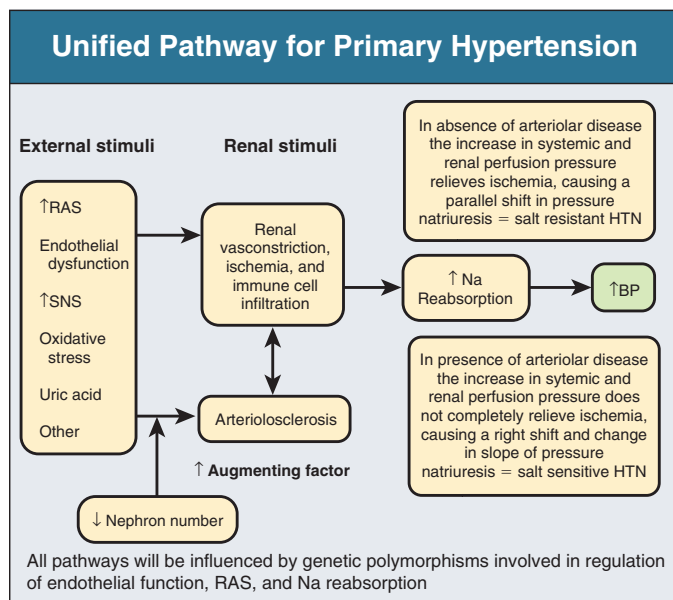

Figure 33.6. Unified pathway for primary hypertension. Hypertension may be hypothesized as occurring in two phases. The first phase is mediated by renal vasoconstriction due to stimuli such as a hyperactive sympathetic nervous system (SNS), hyperuricemia, endothelial dysfunction, or an activated renin-angiotensin system (RAS). This results in a salt-resistant form of hypertension. Whereas hypertension may remain salt resistant, we hypothesize that progressive renal microvascular disease and tubulointerstitial inflammation will develop in many subjects, with a switch to a salt-sensitive phenotype and an increased risk for microalbuminuria. BP, blood pressure; HTN, hypertension.

fructose intake and the rise in hypertension and obesity. In one study of newly diagnosed hypertension in obese adolescents, an elevated uric acid level was observed in nearly 90% of cases. In a small double-blind placebo-controlled study, the lowering of uric acid levels to below 5.0 mg/dl resulted in normal BP in 86% of subjects compared with 3% of controls.¹³ While exciting, further studies are needed before lowering of uric acid can be recommended for treatment or prevention of hypertension or cardiovascular disease.

A hyperactive SNS is also commonly involved in early hypertension, particularly in young or borderline hypertensive patients.¹⁴ Postulated mechanisms include a defect in baroreceptor sensitivity and an increase in SNS response to emotional or work-related stress. Activation of either the systemic or local RAS is also common in hypertension. Whereas plasma renin activity is elevated in 20% of patients, renin activity is either normal (50%) or low (30%) in the majority. However, normal renin activity may be inappropriately high in relation to the total body sodium. Finally, some hypertensive subjects will have elevated plasma aldosterone, especially if the RAS is inhibited with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs).^{15,16} Typically, such subjects are obese and have hyperinsulinemia or some degree of endothelial dysfunction. In these subjects, the aldosteronism is driven by a mechanism other than Ang II or hyperkalemia, and some studies suggest that it may be due to the presence of circulating oxidized fatty acids (especially linoleic acid) or uric acid.

How Does Salt Retention Lead to Hypertension?

An acute infusion of saline administered to animals with experimentally induced hypertension will initially raise blood volume

Figure 33.7 Prevalence of primary hypertension in the United States. The prevalence of primary hypertension (defined as BP >140/90 mm Hg) in the United States has been rising from a prevalence of 11% in 1939 to 31% today.

and cardiac output, but the increase in cardiac output is transient and is replaced by a rise in the systemic vascular resistance, a process that Guyton and associates³ termed autoregulation because they postulated that the vasoconstriction is an adaptive response resulting from the need to reduce unnecessary increments in tissue perfusion. Several mechanisms may account for the rise in systemic vascular resistance. First, volume expansion is known to increase circulating Na^+ , K^+ -ATPase inhibitors (such as ouabain from the adrenal gland) that raise intracellular sodium and facilitate sodium-calcium exchange in the vascular smooth muscle cell.¹⁷ This would lead to a rise in intracellular calcium concentration and stimulate vascular smooth muscle contraction, vasoconstriction, and the rise in vascular resistance. Circulating nitric oxide synthase (NOS) inhibitors have also been documented in some patients with primary hypertension. A small increase in serum sodium concentration may also occur in hypertensive subjects and may stimulate the release of vasoconstrictive substances such as vasopressin, which may have a role particularly in African Americans.¹⁸ Activation of the SNS may also occur in salt-sensitive hypertension in response to a salt load.¹⁹ A possible explanation is that in the setting of tubulointerstitial injury and intrarenal ischemia, the salt load will trigger an intense tubuloglomerular feedback (TGF) signal with activation of the renal afferent SNS, which activates central nervous system (CNS) sympathetic activity.¹⁹ Other mechanisms that could contribute to increased systemic vascular resistance are loss of vasodilatory substances from the kidney, such as kallikrein and medullipin, or the loss of systemic capillaries (microvascular rarefaction).

EPIDEMIOLOGY

Primary hypertension is epidemic. In the United States, the prevalence has increased from 5% to 11% of the population in the early 1900s to 31% (65 million people) today (Fig. 33.7).²⁰ The increase in prevalence, which has also been observed in Europe, is not completely accounted for by the increasing life expectancy in the population. Similarly, hypertension was virtually absent outside Europe and North America until the 1930s, but it has subsequently increased to prevalence rates of 20% to 30% in conjunction with adaptation of the Western diet and lifestyle. By 2025, an estimated 1.56 billion people will have primary hypertension. The increase in hypertension

Risk Factors for Primary Hypertension	
Genetic	Family history Polymorphisms (adducin, endothelial nitric oxide synthase, angiotensinogen, β_2 -adrenoceptor, human G protein β_3 subunit)
Congenital	Low birth weight, low nephron number, maternal hypertension, maternal preeclampsia, maternal malnutrition
Physical	Obesity, older age, African American, African Caribbean, increased heart rate (>83 beats/min), increased emotional stress
Diet/toxin	Increased sodium intake, low potassium intake, low dairy products intake, heavy alcohol intake, low level lead or cadmium intoxication
Metabolic (laboratory-based parameters)	Elevated uric acid, insulin resistance, elevated hematocrit
Other	Low socioeconomic status, urban vs rural

Figure 33.8 Major risk factors for primary hypertension.

correlates with increasing frequencies of obesity, type 2 diabetes, and chronic kidney disease (CKD), suggesting a strong interrelationship.

There are several major risk factors for hypertension (Fig. 33.8). First, the risk for primary hypertension increases with age, with a 65% prevalence in the population at the age of 65 years and 75% at 75 years.²¹ This age-related increase in prevalence of hypertension has been observed in most Western countries but has not been uniformly observed in all populations. Second, hypertension is more common in men, although the prevalence in women may surpass that in men in the postmenopausal years. Certain racial groups are also at increased risk, particularly African Americans and Filipino Americans in the United States and various minority populations throughout the world (such as the Pima Indians, Australian aborigines, and the Maoris). Risk factors for hypertension include obesity, insulin resistance, hyperuricemia or gout, sleep apnea, low socioeconomic status, and increased stress at work. Certain physical features, such as elevated heart rate or an increased BP response to exercise, are also predictive, as is elevated hematocrit.

Genetic factors also contribute (see Etiology/Pathogenesis). Although the inheritance patterns do not follow classic mendelian genetics for a single gene locus, there is evidence that as much as 30% of hypertension may have a genetic basis because of the cumulative effect of multiple susceptibility genes (the polygene hypothesis). An increased risk for hypertension has been associated with genetic polymorphisms involving the immune system and oxidative stress mechanisms (heat shock protein 70 variants and extracellular superoxide dismutase), vasoactive mediators (angiotensinogen, endothelial NOS, prostacyclin synthase, β_2 -adrenoceptor, 20-HETE synthase [*CYP4F2* gene], and G protein β_3), mediators of vascular smooth muscle tone (calcium-dependent potassium channel [*KCNMA1*]), or mediators controlling renal sodium transport (α -adducin and 11 β -hydroxysteroid dehydrogenase type 2, aldosterone synthase, WNK kinases).¹⁹

Hypertension is more likely to occur if the mother has a history of hypertension, obesity, preeclampsia, or malnutrition. These risk factors are all associated with intrauterine growth retardation and low birth weight, both of which predispose to future hypertension as well as diabetes and obesity.

Dietary and other environmental factors may contribute to the risk for hypertension. Obesity (with or without features of insulin resistance and the metabolic syndrome) is a major risk

factor for hypertension. Obesity is increasing in both developing and industrialized countries and parallels the rise in hypertension in these countries. Epidemiologic and interventional studies have linked salt intake with hypertension, although the relationship is best demonstrated in older subjects and in African Americans. Diets low in calcium and dairy products or potassium are also associated with a higher prevalence of hypertension. Increasing potassium intake lowers BP in both experimental and human studies. Finally, certain toxins, most notably low-level lead or cadmium intoxication, are associated with increased frequency of hypertension.

CLINICAL MANIFESTATIONS

Evaluation of a patient with hypertension includes a careful history and physical examination, an evaluation of risk factors for hypertension, a search for potential secondary causes of hypertension, and an evaluation for end-organ damage.

BP should be repeatedly measured on at least three occasions to confirm persistent hypertension by the techniques described in Chapter 32. Home BP monitoring or 24-hour ambulatory BP monitoring (see Chapter 32) is recommended to determine if the hypertension occurs only in the physician's office (white coat hypertension) and rarely to identify masked hypertension, in which elevations in BP occur only outside the physician's office. Because white coat and masked hypertension can be associated with end-organ disease (including left ventricular hypertrophy and microalbuminuria), diagnosis should be followed by assessment of cardiovascular risk factors and frequent re-evaluation of BP.

The history should investigate the onset and duration of hypertension and the presence of a family history of hypertension or cardiorenal disease. The history should identify risk factors for hypertension (obesity, diabetes, physical activity, alcohol, smoking, diet, emotional or work-related stress, and over-the-counter and prescribed medications) and any hypertension-related morbidity. Hypertension is often considered asymptomatic, but there is increasing evidence that it can be associated with reduction in memory and mental performance, and hypertension remains a major risk factor for vascular dementia. Good BP control may both improve mental performance and decrease the risk for development of dementia.^{22,23}

Hypertension, especially stage 2 (see Fig. 33.2), may also be associated with headache (classically occipital and pulsatile). In hypertension emergency, encephalopathy may rarely occur with an acute decrease in mental status or seizures. Rarely, patients may lose vision from papilledema. Severe hypertension may also place individuals at acute risk for myocardial infarction, congestive heart failure with pulmonary edema, aortic dissection, stroke, and renal failure.

Physical examination should include measurement of BP in both arms and a careful cardiac examination. Attention should be focused on both the large vessels (by both palpation and listening for bruits) and the retina to grade the severity of disease in the microvasculature (Fig. 33.9).

Laboratory tests should include hematocrit, electrolyte values, creatinine concentration, calcium and phosphate concentrations, fasting lipid profile (cholesterol and triglycerides), uric acid level, C-reactive protein level, and urinalysis, including a spot urine albumin to creatinine ratio for microalbuminuria. Chest radiography and electrocardiography should also be performed to assess cardiac size and the presence of left ventricular hypertrophy and to look for aortic dilation.

Figure 33.9 Different grades of hypertensive retinopathy. **A**, Mild hypertensive retinopathy, with arteriolar narrowing and arteriovenous nicking. **B**, Moderate hypertensive retinopathy, with cotton wool spots (nerve fiber layer infarcts) and arteriovenous nicking. **C**, Malignant hypertension with papilledema, cotton-wool spots, macular yellow exudates (star formation pattern), and retinal hemorrhages. (Gift J. Kinyoun, Seattle, Washington, USA.)

Figure 33.10 Echocardiogram showing concentric left ventricular hypertrophy. Septal thickness (between large arrows) and posterior wall thickness (between arrowheads) are increased (to 16 mm) in a patient with primary hypertension (normal is 11 mm or less). (Gift of A. Pearlman, Seattle, Washington, USA.)

Additional tests that may be helpful include an estimated GFR and, under certain circumstances, a 24-hour urine sodium and potassium determination. Urinary excretion will correlate closely with intake if the patient is in steady state (the desirable values are <100 mmol/l Na^+ and >100 mmol/l K^+ in 24 hours). A spot urine albumin to creatinine ratio and an echocardiogram may uncover additional evidence of end-organ damage (Fig. 33.10). Note that a spot urine albumin to creatinine ratio is recommended only for those with diabetes or stage 2 or higher CKD. Echocardiography is not recommended for routine use in people with hypertension because of its cost, although it is appropriate for people with cardiac problems.

PATHOLOGY

Primary hypertension has characteristic renal pathology in which there is preferential involvement of the preglomerular arterial vessels, primarily the afferent arteriole and interlobular artery. The classic vascular lesion, seen in 90% of cases, is arterioloscle-

rosis, in which smooth muscle cells of the media in the afferent arteriole are replaced by connective tissue (Fig. 33.11).²⁴ The arteriolar lesions are often associated with the accumulation of hyaline material (plasma proteins) in the subintima (hyalinosis). In addition, there is often evidence of glomerular and tubulointerstitial ischemia with shrinkage of the glomerular tuft, tubular atrophy, and interstitial fibrosis. On occasion, glomerulosclerosis and severe tubulointerstitial injury are seen. In cases of hypertensive emergency, there is a proliferative arteriolopathy, occasionally with fibrinoid necrosis. Concentric layers of connective tissue and cells may give an onion-skin appearance to the intima, which may progress to a total obliteration of the lumen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of primary hypertension requires the elimination of secondary causes, of which the more common include medication (nonsteroidal agents, corticosteroids, sympathomimetics, oral contraceptives), drugs (excessive alcohol intake, cocaine), intrinsic renal parenchymal disease, renovascular disease, and primary aldosteronism from adrenal hyperplasia or tumors. Hyperuricemia may also be a cause of some forms of primary hypertension, especially in the adolescent. A more complete list along with the recommended evaluation for secondary causes is provided in Chapter 32.

NATURAL HISTORY

The major long-term risk of hypertension is cardiovascular disease, which can be separated into pressure-related (stroke, heart failure), atherosclerotic (myocardial infarction), and renal (CKD) etiologies. Hypertension is the most common cause of stroke and congestive heart failure, and the risk increases linearly with BP (Fig. 33.12).²⁵ Other pressure-related morbidities include aortic dissection and cerebral and aortic aneurysms. Increased systolic, diastolic, and pulse pressure all confer risk, although the systolic BP and the pulse pressure are the more important determinants of risk for the pressure-related morbidities. This increased risk is dependent on age (increases with age), sex (greater in males), ethnic origin (greater in African Americans), and other associated risk factors (e.g., diabetes).

Hypertensive heart disease begins with concentric left ventricular hypertrophy associated with supernormal systolic function. Over time, impaired diastolic dysfunction may occur, as

Figure 33.11 Renal pathology in primary hypertension. **A**, A granular pitted kidney of benign nephrosclerosis. **B**, Arteriosclerosis with subintimal hyaline. **C**, Electron micrograph showing hyaline with the accumulation of insudative plasma proteins in the subendothelium of an arteriole. Figure 33.12 Relative risks for stroke (A) and coronary heart disease (B) increase with higher diastolic blood pressure. The stroke data are from seven prospective observational studies and 843 events; the coronary heart disease data are from nine studies and 4856 events. Size of squares is proportional to the number of events in each category; the vertical lines indicate 95% confidence intervals. (Modified with permission from reference 25.)

manifested by slow diastolic filling, which reflects decreased diastolic relaxation. This may progress to congestive heart failure. Nearly 90% of patients with heart failure have a history of hypertension.

Hypertension also confers risk for atherosclerotic-associated morbidities, including coronary heart disease,²⁵ peripheral vascular disease, and carotid atherosclerosis with or without cerebral emboli. In addition to an increased prevalence of hypertension, African Americans also have a 50% greater risk for heart disease.

Kidney Disease

Most patients with newly diagnosed primary hypertension will have normal renal function or stage 1 (GFR >90 ml/min per 1.73 m² with microalbuminuria) or stage 2 (GFR 60 to 90 ml/min per 1.73 m²) CKD with elevated renal vascular resistance.²⁰ Despite relatively normal renal function, renal biopsy, if it is done, usually shows arteriosclerosis and hyaline (see Fig. 33.11).

Before effective antihypertensive agents, proteinuria developed in up to 40% of patients, and as many as 18% developed renal insufficiency over time. Currently, microalbuminuria, which is a marker of vascular disease and cardiovascular risk, occurs in 15% to 30% of patients, and fewer patients develop non-nephrotic or, rarely, nephrotic-range proteinuria.²⁶ The development of microalbuminuria is associated with salt sensitivity, with the loss of nocturnal dipping in BP, and with increased target organ damage (especially left ventricular hypertrophy). Elevations in serum creatinine develop in 10% to 20% of patients with poorly controlled BP, and the risk is greater in African Americans, in the elderly, and in those with higher systolic BP (systolic BP >160 mm Hg).^{27,28} In 2% to 5% with poorly controlled systolic BP (i.e., >160 mm Hg), progression to renal failure will occur during the subsequent 10 to 15 years (Figs. 33.13 and 33.14). Despite the relative infrequency for progression of hypertension to end-stage renal disease (ESRD), hypertension is recorded as the second most common cause of ESRD after diabetes in the United States and Europe. Furthermore, almost all patients with diabetes have hypertension when they start dialysis.

The incidence of ESRD secondary to hypertension is fourfold to sixfold greater in African Americans.²⁹ Renal biopsy specimens of African Americans with hypertension tend to show more severe forms of hypertensive injury, with more prominent vascular changes and increased frequency of segmental and global glomerulosclerosis. Whereas some of these vascular changes may relate to the presence of certain transforming growth factor β polymorphisms or higher uric acid levels that are common in this population, studies suggest that the increased frequency of glomerulosclerosis may be due to polymorphisms in the gene encoding apolipoprotein L-1 (APOL-1), which became prevalent in the African population since it confers protection from African sleeping sickness (trypanosomiasis) but which has the disadvantage of increasing the risk for focal segmental glomerulosclerosis (FSG) in the presence of hypertension.^{30,31} The

Figure 33.13 End-stage renal disease and blood pressure (ESRD). Incidence of ESRD related to baseline blood pressure in the MRFIT study. Mean follow-up was 16 years. (From reference 27.)

Figure 33.14 Effect of race on incidence of end-stage renal disease (ESRD) in hypertension. The rate of ESRD in African American and Caucasian hypertensive veterans. (Kaplan-Meier estimates). (From reference 28.)

observation that much of the increased risk for renal failure in the African American may be accounted for by APOL-1 polymorphisms raises the question of how often stage 1 hypertension itself may cause ESRD in this cohort.

Effect of Antihypertensive Therapy on the Natural History of Hypertensive Cardiovascular Disease and Kidney Disease Progression

According to a recent report, only 59% of subjects with hypertension in the United States are receiving treatment, and only 34% have their BP under adequate (<140/90 mm Hg) control.² Although there has been significant reduction in the age-adjusted death rate for stroke and coronary artery disease since the early 1980s as a result of better BP control (and better treatment of other risk factors, such as hyperlipidemia), heart disease and stroke remain the first and third leading causes of death in the United States. This emphasizes the importance of identifying and treating patients with hypertension.

Antihypertensive therapy reduces cardiovascular complications in patients with stage 2 hypertension, although there are far fewer data to support this for stage 1 hypertension (Fig. 33.15).³² The reduced risk is most significant for stroke and congestive heart failure but also occurs for myocardial infarction. In all trials, to date, it is the group with the best overall BP control that has the best result.³³ One exception to this are the data from the recent ACCOMPLISH trial, in which both groups had similar BP control, yet the group initially randomized to an ACE inhibitor with a calcium antagonist had a 20% cardiovascular risk reduction compared with the ACE inhibitor plus diuretic group.³⁴ Note that almost all people with some level of kidney disease will require two or more medications. Diuretics are better initially for lowering BP and required in those with renal insufficiency but are not considered initial agents of choice by any guidelines except those from the United States.

The effect of antihypertensive therapy on the progression of renal disease secondary to hypertension is more controversial. In

Figure 33.15 Meta-analysis of effect of antihypertensive agents on cardiovascular outcomes in hypertensive subjects. The analysis was based on 42 clinical trials that included 192,478 patients randomized to seven major treatment strategies, including placebo. CHF, congestive heart failure; CI, confidence interval; CVD, cardiovascular disease; RR, relative risk. *The no treatment comparison group includes placebo-treated controls, participants not treated in open trials, and participants receiving usual care. (Reprinted with permission from reference 32.)

Meta-Analysis of Effect of Antihypertensive Agents On Cardiovascular Outcomes in Hypertensive Subjects				
Outcome	No. of Trials	Effects Model	RR (95% CI)	P Value for Heterogeneity
Coronary heart disease	24	Fixed Random	0.86 (0.80-0.93) 0.87 (0.80-0.94)	.55 .55
Stroke	23	Fixed Random	0.69 (0.64-0.74) 0.68 (0.61-0.76)	.004 .004
CHF	7	Fixed Random	0.54 (0.45-0.66) 0.60 (0.49-0.74)	.66 .80
Major CVD events	28	Fixed Random	0.78 (0.74-0.81) 0.73 (0.62-0.87)	<.001 <.001
CVD mortality	23	Fixed Random	0.84 (0.78-0.90) 0.84 (0.78-0.90)	.10 .10
Total mortality	25	Fixed Random	0.90 (0.85-0.95) 0.90 (0.85-0.95)	.58 .59

Figure 33.16 Ramipril is superior to amlodipine in reducing renal events in hypertensive African Americans with mild to moderate renal insufficiency. The ACE inhibitor ramipril resulted in fewer renal end points (proteinuria, decline in renal function, ESRD, or death) compared with the dihydropyridine calcium channel blocker amlodipine in the African American Study of Kidney Disease. ACE, angiotensin-converting enzyme; ESRD, end-stage renal disease. (Reprinted with permission from reference 36.)

the Multiple Risk Factor Intervention Trial (MRFIT), in which diuretics and β -blockers were primarily used to control BP, slowing or stabilization of renal function was observed only in nonblack as opposed to African American men.³⁵ In the African American Study of Kidney Disease, the use of an ACE inhibitor (ramipril) was found to be more effective at slowing renal progression compared with either the dihydropyridine calcium channel blocker amlodipine (Fig. 33.16) or metoprolol.^{36,37} However, both this study and others have failed to show superior protection with tight BP control compared with conventional BP targets in subjects with renal disease secondary to hypertension.^{37,38} Masked hypertension may be a confounder to these results; a subanalysis of ambulatory BP showed inadequate 24-hour BP control in more than 70% of the cohort. Masked hypertension and nondipping (i.e., the lack of fall in BP with sleep) were the two most common reasons for poor BP control.³⁹ Further studies regarding the dosing and timing of antihypertensive treatment are being performed to evaluate changes in overall BP control. In contrast, *post hoc* analyses of trials show that subjects with diabetic renal disease or with proteinuric (>300 mg/day) renal disease, including that due to hypertension, do appear to benefit from lower BP goals in terms of renal protection. On the basis of current evidence, achieved BP levels should be below 140 mm Hg systolic for nonproteinuric hypertensive renal disease and below 130/80 mm Hg in those with diabetes and hypertensive subjects with proteinuria.⁴⁰

Finally, a number of studies suggest that thiazide diuretics are associated with worsening of renal function in subjects with hypertension. In the European Working Party on High Blood Pressure in the Elderly trial, a significantly higher incidence of impaired renal function was found in those receiving diuretics compared with placebo.⁴¹ In the Systolic Hypertension in the Elderly trial, serum creatinine increased significantly in the subjects treated with thiazide diuretics compared with placebo.⁴² In

the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the chlorthalidone-treated group showed a statistically worse renal function than either the amlodipine- or lisinopril-treated group at both the 2- and 4-year end points.⁴³ Whereas this could probably be accounted for by volume depletion in many cases, diuretics have been shown to induce mild renal injury in various animal models, possibly as a consequence of hypokalemia, hyperuricemia, and stimulation of the renin-angiotensin-aldosterone system related to the reduction in renal perfusion pressure.⁴⁴

Can Primary Hypertension Spontaneously Remit?

Before the age of 60 years, as many as 15% to 20% of patients with prehypertension may become normotensive spontaneously. Furthermore, in patients with established hypertension who have good BP control for 5 years with treatment, as many as 20% to 40% can be withdrawn from therapy successfully, especially if they have stage 1 hypertension and adhere to salt restriction and weight reduction. This suggests that the processes that mediate hypertension are at times reversible.

Nonpharmacologic Prevention and Treatment of Hypertension

Brian Rayner, Karen E. Charlton, Estelle V. Lambert, Wayne Derman

Lifestyle changes, including a combination of increased fat and refined carbohydrate intake and reduced physical activity, have resulted in an epidemic of obesity, type 2 diabetes mellitus, and hypertension. The epidemic is evident worldwide and often is greatest in underserved and indigenous populations.

Adoption of healthy lifestyles is critical for both the prevention of high blood pressure (BP) and its management. According to the Seventh Report of the Joint National Committee on Prevention, Evaluation, and Treatment of High Blood Pressure (JNC 7),¹ lifestyle interventions lower BP, enhance efficacy of antihypertensive medication, and lower overall cardiovascular risk. The lifestyle changes that are widely agreed to lower BP and cardiovascular risk are (1) smoking cessation, (2) weight reduction, (3) moderation of alcohol intake, (4) physical exercise, (5) reduction of salt intake, (6) increase in fruit and vegetable intake, and (7) decrease in saturated and total fat intake.¹

Interventions may have efficacy similar to that of single-drug therapy (Fig. 34.1). However, lifestyle changes should not delay the initiation of drug therapy in patients at higher cardiovascular risk.

PREVENTION

The importance of primary prevention has been underscored by the recognition that the treatment of hypertension is expensive, the control of BP in hypertensive individuals does not restore cardiovascular risk to normal, and the majority of hypertensive individuals do not reach goal BP. The most important subjects to target are those with prehypertension (defined by JNC 7 as 120 to 139/80 to 89 mm Hg; see Chapter 33).¹ Individuals with prehypertension have an increased prevalence of early vascular damage, an increased risk of incident hypertension, and an increased risk of cardiovascular events compared with those with optimal levels (<120/80 mm Hg).² The JNC 7 recommends lifestyle changes in all patients with prehypertension to prevent hypertension and to reduce their cardiovascular risk.¹

The contribution of body weight, physical inactivity, and dietary factors to the prevalence of hypertension in Europe and the United States has been quantified in a meta-regression analysis.³ Being overweight made the largest contribution to hypertension, with population-attributable risk percentages (PAR%) between 11% (Italy) and 25% (United States). PAR% was 5% to 13% for physical inactivity, 9% to 17% for high sodium intake, 4% to 17% for low potassium intake, and 4% to 8% for low magnesium intake. The impact of alcohol was small (2% to 3%) in all populations. PAR% varied among populations for inadequate intake of calcium (2% to 8%), coffee (0% to 9%), and fish fatty acids (3% to 16%).

WEIGHT LOSS

Obesity is epidemic throughout the world, and 65% of the adult population in the United States is either overweight (body mass index [BMI], 25.0 to 29.9) or obese (BMI ≥ 30).⁴ Obese individuals have a threefold increased prevalence of hypertension. Possible mechanisms for obesity-induced hypertension include overactivity of the sympathetic nervous system (RAS), hyperinsulinemia (which may increase renal sodium reabsorption), hyperuricemia, activation of the renin-angiotensin system, and sleep apnea. Abdominal or visceral obesity is a greater predictor of both hypertension and cardiovascular risk than is a predominant lower body fat distribution. Abdominal obesity is defined as a waist circumference of more than 88 cm (35 inches) in women and more than 102 cm (40 inches) in men. These reference values were developed in Caucasian populations, and differing criteria may be more appropriate for other ethnic groups.

In obese hypertensives or those with high-normal BP, weight loss of as little as 4 to 5 kg is often associated with a significant reduction in BP. Weight loss is one of the most effective nonpharmacologic interventions to reduce BP.⁵ A meta-analysis has demonstrated that a weight reduction of 5.1 kg reduced systolic BP by 4.44 mm Hg and diastolic BP by 3.57 mm Hg.⁶ A rule of thumb is that for every kilogram lost, there is a reduction of 1 mm Hg in both systolic and diastolic BP. To minimize the risk of relapse and to maintain sustainability of the weight loss program, the initial target should be 5% to 10% of current weight, or 1 to 2 BMI units. Marked oscillations in weight should be avoided because this increases the risk for development of hypertension in obese, normotensive subjects.⁷ A randomized trial of the effectiveness of four popular diets on sustained weight loss and cardiovascular disease risk reduction concluded that a variety of diets can similarly reduce weight and BP, but only a minority of individuals can sustain high dietary adherence. High-protein diets such as the Atkins diet, often advocated for weight loss by the media and lay public, have no place in hypertensive patients with renal disease.

Weight reduction should be accompanied by recommendations to increase physical activity unless it is contraindicated. Bariatric surgery, pharmacologic interventions for weight loss (e.g., sibutramine, orlistat), and very low calorie (liquid) diets or meal replacement diets may be useful to achieve weight loss in some patients, but always as an adjunct to rather than a substitute for lifestyle modification.

PHYSICAL ACTIVITY

Physical inactivity is associated with at least a 1.5- to 2-fold higher risk of hypertension and coronary heart disease.⁸ Regular

Lifestyle Modifications for the Prevention and Management of Hypertension (Joint National Committee 7 Guidelines ¹)		
Modification	Recommendation	Average Systolic BP Reduction Range Achieved with Intervention*
Weight reduction	Maintain normal body weight (BMI = 18.5–24.9 kg/m ²)	5–20 mmHg/10 kg
DASH eating plan	Adopt a diet rich in fruits, vegetables, and low-fat dairy products with reduced content of saturated and total fat	8–14 mmHg
Dietary sodium restriction	Reduce dietary sodium intake to 100 mmol/day (2.4 g sodium or 6 g sodium chloride)	2–8 mmHg
Aerobic physical activity	Regular aerobic physical activity (e.g., brisk walking) at least 30 min/day, most days of the week	4–9 mmHg
Moderation of alcohol consumption	Men: limit to 2 drinks [†] per day; women and lighter-weight persons: limit to 1 drink per day	2–4 mmHg

Figure 34.1 Lifestyle modifications for the prevention and management of hypertension (Joint National Committee 7 guidelines¹). BMI, body mass index; BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension. *Effects are dose and time dependent. †One drink = ½ oz or 15 ml ethanol (e.g., 12 oz of beer, 5 oz of wine, 1.5 oz of 80-proof whiskey).

physical activity is known to lower the risk of all-cause morbidity and mortality and provides the basis for public health recommendations to exercise at least 30 minutes per day.

Exercise Training Dose Response

In a meta-analysis of studies involving more than 1500 patients, exercise training in normotensive subjects has been shown to reduce systolic and diastolic BP by 3.0 ± 1 and 1.7 ± 1 mm Hg, respectively.⁹ In hypertensive subjects, the effect of exercise training is even more marked (a reduction of 7.8 ± 3.5 and 5.8 ± 2.0 mm Hg for systolic and diastolic BP, respectively). Studies in hypertensive subjects have shown that the benefit of exercise on BP is maximal with 90 minutes of exercise per week, after which there was no further improvement.¹⁰ Furthermore, only a modest amount of exercise was needed to reduce BP in patients with hypertension (>30 min/wk).

Fagard⁹ found no benefit of increasing exercise intensity on BP reduction with exercise training, as long as intensity ranged between 40% and 70% of maximal, age-predicted heart rate. This contrasts with the acute effects of exercise on the attenuation of postexercise BP. Exercise of higher intensity (75% maximum) was associated with a more marked and prolonged reduction in BP in the postexercise window compared with lower intensity exercise (50% maximum).¹¹ In addition, regular exercise prevents the development of left ventricular hypertrophy that is independent of BP in young stage 1 hypertensive subjects.¹²

Mechanisms

In the acute postexercise period, the reduction in BP has been linked to a sympathetic inhibition and increased release of vasodilator substances.¹³ The mechanisms by which chronic exercise lowers BP are less well understood but include reductions in systemic vascular resistance secondary to neurohumoral and structural adaptations. Chronic exercise is also associated with a loss of weight and a reduction of serum uric acid levels, both of which could potentially lead to a reduction in BP.

Antihypertensive Medication and Guidelines for Exercise

Exercise guidelines for patients with hypertension are shown in Figure 34.2.¹⁴ β -Blockers decrease exercise tolerance. β -Blockers and diuretics may also alter thermoregulation in hot environments and provoke hypoglycemia. Patients using these medications should be educated about exercising in the heat, clothing, the role of adequate hydration, and methods to prevent hypoglycemia.^{15,16} Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and calcium channel blockers may be better suited for patients who exercise frequently or athletes with hypertension.

For patients undergoing supervised exercise training, the monitoring of postexercise BP may be helpful so that medications may be adjusted appropriately, considering the likelihood of postexercise hypotension. Particular care should be taken with patients planning to exercise in a hot environment.

DIET

Salt Intake

Epidemiologic studies have demonstrated that the prevalence of hypertension is directly related to the dietary salt intake in societies throughout the world in whom the intake is above 50 to 100 mmol/day or 3 to 6 g sodium chloride (Fig. 34.3).¹⁷ Where daily intake is below that range, hypertension is rare. Salt intake also plays an important role in the age-related increase in BP (Fig. 34.4).¹⁸

Not all individuals respond similarly to high salt intake. Salt sensitivity describes a group of individuals who significantly decrease or increase their BP during periods of salt restriction or loading, respectively. Conversely, salt-resistant subjects have minimal BP response to changes in salt intake,¹⁹ and it has been argued that a high salt intake may not be detrimental in salt-resistant subjects and that salt restriction should not be universally recommended. However, a prospective study of 1173 men and 1263 women in Finland found that coronary heart disease,

Practical Guidelines for Exercise in Patients with Hypertension

All apparently healthy individuals should undergo pre-exercise screening to determine health risk status. The American College of Sports Medicine (ACSM) recognizes that two or more of the following risk factors increase the risk associated with exercise, and individuals should undergo pre-exercise graded exercise testing. Risk factors include male gender (older than age 45 years) or female gender (older than 55 years); serum cholesterol concentrations >5.2 mmol/l; impaired glucose tolerance or diabetes mellitus; smoking; obesity ($\text{BMI} \geq 30$); inactivity; and family history of cardiovascular disease.

Patients with uncontrolled hypertension should embark on exercise training only after evaluation and initiation of therapy. Furthermore, patients should not participate in an exercise training session if resting systolic blood pressure is >200 mmHg or diastolic blood pressure is >115 mmHg.

Many patients with hypertension are overweight and should therefore be encouraged to follow a program that combines both exercise training and restricted calorie intake.¹⁴

Type of exercise: this should be predominantly endurance physical activity including walking, jogging, cycling, swimming, or dancing. This should be supplemented by resistance exercise that can be prescribed according to the ACSM or American Heart Association guidelines.¹⁵

Frequency of exercise: most or preferably every day.

Intensity of exercise: moderate intensity at 40%–60% of VO_2 peak.

Duration of exercise: >30 minutes of continuous or accumulated moderate physical activity daily.

Figure 34.2 Practical guidelines for exercise in patients with hypertension. BMI, body mass index. (Modified from references 14 and 15.)

Figure 34.3 Relationship of salt intake with frequency of hypertension in different populations. D, data from Dahl. F, data from the Framingham study. (Modified from reference 17.)

cardiovascular disease, and all-cause mortality increased significantly with increasing 24-hour urinary sodium excretion, independently of BP and other cardiovascular risk factors.²⁰ In a combined analysis of the Trials of Hypertension Prevention (TOHP) I and II, salt restriction not only reduced BP but also resulted in a 25% reduction in cardiovascular events.²¹ Experimental studies in mice suggest that salt intake accelerates atherosclerosis by the intravascular generation of angiotensin II.²²

There is no easy way to identify a patient with salt sensitivity, but a suppressed plasma renin activity may be a useful marker. Several studies have shown a higher frequency of salt sensitivity in the following groups of patients:

- African Americans;
- elderly people;
- obese subjects (not in all studies);
- type 1 and 2 diabetics;
- patients treated with calcineurin inhibitors; and
- patients with chronic kidney disease.

Figure 34.4 Blood pressure changes with age and salt intake. The increase in systolic blood pressure with age correlates with a higher salt intake in two Polynesian populations. In men of Rarotonga Island in Polynesia, where the sodium intake averages 130 mmol/day, systolic blood pressure increases with age. In contrast, it remains constant in men from Pukapuka Island, where the sodium intake averages 50 to 70 mmol/day. (Modified from reference 18.)

Salt sensitivity is observed in 75% of hypertensive African Americans compared with about 50% of Caucasian hypertensives¹⁹ and increases with age in both normotensive and hypertensive populations (Fig. 34.5).²³ There is convincing reason to recommend universal salt restriction in all older people. A randomized, controlled trial in British people aged 60 to 78 years who were not receiving antihypertensive medication found that a modest salt restriction from 5 g to 10 g per day resulted in an impressive reduction of BP of 7.2/3.2 mm Hg during a 4-week period.^{5,24} Importantly, unlike in studies of younger subjects, similar decreases in BP were seen for both normotensive and hypertensive subjects. These findings are consistent with predictions that a reduction in sodium intake of 50 mmol/day (about 3 g of salt) in older people would lower systolic BP by an average

Figure 34.5 Increase in magnitude of salt sensitivity with increasing age. Salt sensitivity (determined by a standardized test evaluating the change in blood pressure from a volume-expanded to a contracted state) increases proportionately with age in both hypertensive and normotensive subjects (bars indicate standard error of the mean; * $P < .05$). (Modified from reference 19.)

of 5 mm Hg,²⁵ which is estimated to reduce stroke by 36% during 5 years.

Putative mechanisms for salt sensitivity are alterations in circulating levels of (or renal responses to) atrial natriuretic factor, kallikrein, prostaglandins, and nitric oxide; increased levels of norepinephrine; abnormal suppression of both renin and aldosterone; genetic mechanisms; congenital reduction in nephron number; and acquired renal microvascular and tubular injury.^{19,26}

The JNC 7 guidelines recommend a sodium intake of less than 100 mmol/day (6 g sodium chloride)¹; the World Health Organization and Food and Agriculture Organization of the United Nations recommend less than 5 g sodium chloride per day as a population goal, while ensuring that the salt is iodized.²⁷ Avoidance of added salt and salt-rich processed foods can reduce intake from 9 g to about 6 g/day. Further reduction in salt requires specialized dietary counseling. Despite these recommendations, long-term studies have reported only small reductions in BP associated with salt restriction (an average of only 1.1/0.6 mm Hg).²⁸ These results undoubtedly reflect limited compliance, but this can be improved by regular contact with the patient, dietetic counseling, and educational sessions. Measurement of 24-hour urinary sodium is useful to check adherence with salt restriction (calculated as urine sodium [mmol/day] \times 0.0585 = grams NaCl/day).

Population-Based Strategies to Lower Salt Intake

One of the most cost-effective ways to lower salt intake in the general population is to reduce salt in processed foods. This approach was effective in lowering the BP in drug-treated hypertensives in a low-income community setting in South Africa through the modification of the salt content of a small number of commonly consumed foods, including bread.²⁹ In Belgium, the reduction in the salt content of bread between the mid-1960s and the early 1980s was accompanied by marked reductions in 24-hour urinary sodium excretion. In recognition of the need for a concerted global effort to reduce population-wide salt intake,

Figure 34.6 Potassium supplementation lowers blood pressure in hypokalemic hypertensive patients. Treatment with potassium chloride (60 mmol/day potassium for 6 weeks) resulted in an increase in serum potassium concentration and a decrease in mean arterial pressure in hypertensive patients taking thiazide diuretics. (Redrawn from reference 31.)

a World Health Organization Forum and Technical meeting in 2006 recommended an integrated approach incorporating a commitment by the food industry to product reformulation, increased consumer awareness, and social marketing around salt and health issues.³⁰

Potassium Intake

One of the confounding factors of the relationship of salt and BP has been the inverse relationship between the intake of salt and potassium. Typically, diets with a high salt intake are relatively deficient in potassium (and calcium); but in those who consume little salt, the potassium (and calcium) intake is high. These disparate groups also differ in other factors, such as physical activity, industrialization of the society, and racial and genetic characteristics.

In normotensive subjects with an average potassium intake above 1.95 g/day (50 mmol/day), potassium supplementation has no significant effect on BP. However, among hypertensive subjects who are potassium deficient because of diuretic treatment or low potassium intake, potassium supplementation lowers BP (Fig. 34.6).³¹ The Dietary Approaches to Stop Hypertension (DASH) diet lowers BP and is high in potassium because of the high fruit and vegetable content and inclusion of low-fat dairy products (Fig. 34.7).³² However, the synergistic effect of the various food groups in the DASH diet makes it difficult to ascertain the contribution of the individual nutritional components. The mechanisms by which a low-potassium diet may contribute to hypertension are complex and poorly understood. They may relate to stimulation of intrarenal angiotensin (Ang) II, oxidants, and endothelin; inhibition of intrarenal nitric oxide and prostaglandins; and induction of renal ischemia.

Dietary Approaches to Stop Hypertension (DASH) Diet*				
Food Group	Daily Servings	Serving Sizes	Examples and Notes	Significance to the DASH Diet Pattern
Grains and grain products	7–8	1 slice bread 1/2 cup dry cereal 1/2 cup cooked rice, pasta, or cereal	Whole-wheat bread, muffin, pita bread, bagel, cereals, oatmeal	Major sources of energy and fiber
Vegetables	4–5	1 cup raw, leafy vegetables 1/2 cup cooked vegetables 6 oz vegetable juice	Tomatoes, potatoes, carrots, peas, squash, broccoli, turnip greens, kale, spinach, artichokes, green beans, sweet potatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4–5	1 medium fruit 1/4 cup dried fruit 6 oz fruit juice 1/2 cup fresh, frozen, or canned fruit	Apricots, bananas, dates, oranges, orange juice, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or nonfat dairy foods	2–3	8 oz milk 1 cup yogurt 1.5 oz cheese	Skim or low-fat (2%) milk, skim or low-fat buttermilk, nonfat or low-fat yogurt, nonfat or low-fat cheeses	Major sources of calcium and protein
Meats, poultry, and fish	≤2	3 oz cooked meats, poultry, or fish	Select only lean meats; trim away visible fats; broil, roast, or boil instead of frying; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	4–5 wk	1.5 oz 1/3 cup nuts 1/2 oz or 2 tablespoons seeds 1/2 cup cooked legumes	Almonds, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils, split peas	Rich sources of energy, magnesium, potassium, protein, and fiber

Figure 34.7 Dietary Approaches to Stop Hypertension (DASH) diet. *The DASH eating plan shown is based on 2000 kcal/day (8400 kJ/day). Depending on energy needs, the number of daily servings in a food group may vary from those listed. (Modified from the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.)

In the TOHP I and II trials, a higher sodium to potassium excretion ratio (implying a high-salt and low-potassium intake) was more strongly associated with subsequent cardiovascular events than either urinary sodium or potassium excretion alone.³³ Overall, it appears to be beneficial to optimize potassium intake in hypertensive humans to minimize hypokalemia, being careful to avoid the risk of hyperkalemia in subjects with renal impairment or in other susceptible individuals. If renal function is normal, optimal potassium intake is 80 to 120 mmol/day.

Calcium and Dairy Food Intake

Cross-sectional population surveys of self-reported nutrient intake suggest an inverse relationship between calcium intake and BP. The relationship is more convincing at low levels of calcium consumption (<300 to 600 mg/day). There may be a threshold of 700 to 800 mg/day, above which any further reduction in BP is attenuated. A meta-analysis of randomized calcium supplementation trials (mostly with 1 or 1.5 g calcium/day) has demonstrated reductions in systolic BP (−0.9 to −1.7 mm Hg) that are of little clinical importance.³⁴ Although calcium in milk may contribute to BP lowering, dairy products may lower BP by other mechanisms. Biologically active peptides formed during the milk fermentation process, such as the casein-derived tripeptides isoleucine-proline-proline and valine-proline-proline, have ACE-inhibiting properties. These milk-derived tripeptides have been shown to reduce BP by 4.8 mm Hg and 2.2 mm Hg for systolic and diastolic BP, respectively.³⁵ Vitamin D, which is often added to milk, may also help reduce BP by reducing renin expression. At present, the American Heart Association and JNC 7 do not recognize dairy consumption as a dietary approach to the prevention and management of hypertension. Nevertheless,

low-fat dairy products are recommended as an integral part of the DASH diet.

Magnesium Intake

A weak inverse relationship has been reported between dietary intake of magnesium and BP. Nevertheless, in a meta-analysis of 20 randomized clinical trials,³⁶ magnesium supplementation had an insignificant effect on BP. Magnesium has been shown to influence cardiac function and rhythm; therefore, JNC 7 has recommended an adequate intake of magnesium pending more definitive information.¹ The optimal levels of magnesium intake are not yet established.

Other Micronutrients and Bioactive Food Components

The inverse association between fruit and vegetable intake and BP and other cardiovascular risk factors is well established. The biologic effects of certain flavonoids and related phenolic compounds present in these foods are receiving increasing attention. Regular consumption of flavanol-rich foods, such as cocoa products, tea, and red wine, has been shown to be associated with decreased BP. Foods rich in garlic may also have beneficial effects on BP.³⁷

Dietary Fats and Sugars
